This paper is written with the intention of bringing to the busy ophthalmologist a rapid staining technique for the demonstration of trachoma inclusions. This method is not only rapid but simple both in technique and in the reagents necessary. The need for a short cut in a busy practice was forcibly brought to my attention by two cases which I recently saw.

One was the case of a 49-year-old white woman, a native North Carolinian, who has not been out of eastern North Carolina for several years. In September, 1947, she began having pain, photophobia, and redness of the left eye. She immediately sought the aid of a practitioner who treated her for a simple conjunctivitis.

After several weeks of treatment she was referred to an ophthalmologist who made the diagnosis of uveitis, which apparently was quite correct. This was treated for several months and, in January, she was told that the uveitis had cleared but that she had another condition.

The attending physician made many tests,

all of which cost valuable time and money, but at the end of a month of X-ray studies, laboratory tests, and consultation, the diagnosis was still undetermined.

Being a United States Navy dependent, she sought aid at this hospital. Upon seeing her eye, one could not but notice a pannus which had grown down at least 3 mm. upon the cornea. The typical cobblestones of trachomatous conjunctivas were present on both upper and lower lids and also involved the caruncle. Conjunctival scrapings done at this time revealed the typical inclusions of trachoma.

The second case is that of a 23-year-old marine who stated that in December, 1946, upon returning from maneuvers in the Caribbean he first noticed pain, redness, and blurring of vision in the right eye. He was admitted to the dispensary at his activity under the diagnosis of corneal ulcer and was treated with penicillin, hot compresses, and atropine.

He did not improve, so was transferred to a naval hospital where he was treated similarly with the exception that the ulcer was repeatedly cauterized with trichloracetic acid. It is noted in his previous write-up that he had recurrent ulcers at various points on the cornea.

He showed no improvement under this treatment and it was felt advisable to transfer him to another hospital. Here he was treated off and on with sulfadiazine in small doses, penicillin, atropine, hot compresses, typhoid vaccine, sterile-milk injections, X-ray therapy, and radium. He had numerous consultations and was found by the urologist to have chronic prostatitis. The diagnosis was then made of nummular keratitis secondary to chronic prostatitis. He was massaged and given more sulfa and penicillin but to no avail.

After eight months in the hospital the cornea finally cleared enough to send the man back to duty, and it was felt that if the prostate condition would remain quiescent the eye would not flare up.

At this time his vision was 20/40 and he had an opacity in the center of the cornea about 4 mm. in diameter. He states that his eye was still red and still felt irritated. The eye did remain rather quiescent until April 9, 1948, when he was hospitalized because of acute laryngitis. At this time the same symptoms returned and a large ulcer was noted in the center of the cornea. He was then referred to me for consultation.

Upon examining the eye, there was seen an ulcer, 3 mm. in diameter, in the center of the cornea encircled by a large area of opacification which extended through the stroma. There was marked engorgement of all the blood vessels of the eye and quite a great deal of pain. At the upper margin of the limbus there was noted a small pannus growing down upon the cornea (this condition had been discovered previously but it was felt that it was consistent with the changes of nummular keratitis). Vision at this time was limited to hand motion at three feet. Scrapings of the conjunctiva at this time revealed the epithelial cells to be loaded with inclusions typical of trachoma.

TECHNIQUES OF STAINING

After the scraping has been made and spread upon a clean glass slide it is allowed to fix by drying in the air. Then the slide is flooded by Wright's stain and allowed to stand the prescribed time for that particular solution, following which it is neutralized with distilled water. At the end of this neutralizing period it is washed with tap water and allowed to dry. It is then ready to examine under oil. The entire time for this procedure in our laboratory is 7½ minutes —3½ minutes for the Wright's stain and 4 minutes for the buffered mixture. However, this time varies with the solution of Wright's stain used.

This staining technique seems to me to be a boon both to the physician and to the anxious patient, since it is easily carried out in the office and may be included as a routine procedure in practice.

If one were to compare the results of this method with those of the Giemsa stain, it would be found that the inclusions stain blue in both methods but the Wright's stain gives a lighter blue. It would also be found that the nuclei of the epithelial cells stain a rather definite purple which is in contrast to the nuclei poorly stained with Giemsa stain. The time element is the big factor. Since Giemsa stain takes 24 to 48 hours and, in addition, is very sensitive to pH changes, it is not practical as an office test. On the other hand, the Wright's stain technique takes from 7 to 10 minutes and is as simple as a differential blood-smear stain.

The technique of demonstrating the inclusions in these cases has also been used in several cases of inclusion blenorrhea and seems to give ideal results in both.

SUMMARY

1. Two cases of trachoma are presented which were relatively far advanced. The loss of vision, time, and money could have been prevented by examining the conjunctival scrapings of these patients earlier.

2. A rapid staining technique is described for the benefit of the busy ophthalmologist. It can be done in the same manner as a differential blood smear.

3. A comparison is drawn between the Giemsa stain and the Wright's stain.

THE BILATERAL SLAB-OFF*

R. L. SCHMIDTKE, M.D.
Saint Paul, Minnesota

The use of a unilateral "slab-off" for the equalization of the prismatic effect in cases of anisometropia is not new to the ophthal-

mologist and optician, but, to my knowledge, the use of a bilateral "slab-off" for the elimination of the prismatic effect in presbyopic patients who wear a moderately high myopic correction (myopia of about 5 to 10 diopters) has never been reported in the literature.

Several years ago a patient reported for a refraction and during the interview he complained that, since getting his first bi-
Fig. 1 (Schmidtke). The principle of grinding a bilateral "slab-off."

focals, he had been uncomfortable because, as he stated, he had a feeling of looking around the lower edge of his glasses.

During the refraction it occurred to me that this patient's symptoms were due to the prismatic effect produced by his moderately high myopic correction when using his presbyopic add for near vision. In an effort to make this patient more comfortable a flat-top bifocal segment combined with a bilateral "slab-off" was incorporated in his final prescription.

After wearing these glasses for more than a year, this patient reports that he has never had such a comfortable pair of glasses. Since then, I have prescribed this type of lens for a number of myopic patients, all of whom report greater eye comfort.

Without encroaching too much upon the optician's field I will briefly discuss the principle of grinding such a lens (fig. 1).

(A) is a diagrammatic cross section of the conventional myopic lens incorporating a flat-top type bifocal segment.

(B) is a diagrammatic cross section of this same lens into which a prism of appropriate strength and base up has been incorporated so that the optical center has been shifted from a point 2-mm. above the segment to 4-mm. below the top of the segment, thus superimposing the optical center of the distance lens over the optical center of the bifocal segment. Such a lens would be fine for close work but could not be tolerated for distant vision.

(C) is a diagrammatic cross section of the finished lens. Grinding off the prism above the top of the segment produces a new optical center for the distant part of the lens, 2-mm. above the segment, without disturbing the optical set-up for near vision, thus giving the wearer a pair of ophthalmic lenses with two optical centers—one for distant and one for near vision.

If properly made, ophthalmic lenses in which a "slab-off" has been incorporated are no more unattractive than conventional bifocals of the same power.

In cases of high myopia (myopia of 10 diopters or more) requiring a presbyopic near add, this type of lens has no advantage over the "double-myo" lens.

BIOMICROSCOPY WITH POLARIZED LIGHT

DR. GEORGES KLEEFELD discussed this subject during the instruction period.

PRESENT STATUS OF DIABETIC RETINOPATHY

DR. GEORGE ANDERSON said that diabetic retinopathy represents universal retinal vascular disease rather than arterial degeneration alone. Rupture of fragile capillary micro-aneurysmal dilatations has been described. Small, round, deep hemorrhages are probably the most characteristic feature of this specific retinopathy especially in the absence of systemic hypertension.

The duration of the diabetes rather than the age of the patient is the definitive factor. Juvenile diabetics of long duration (15 years) are especially susceptible. Only 8 percent of 200 of Priscilla White's juvenile diabetics between the ages of 20 and 39 years, who had had the disease for 15 years or more, escaped vascular degeneration (85 percent of these had retinal sclerosis; 80 percent, retinal hemorrhages).

In this series, freedom from evidence of vascular degeneration occurred only in those patients who had been well controlled. Careful analysis points to the fallacy of the argument that control of the diabetes makes little or no difference. It is almost impossible to attain 100-percent steady chemical control of the diabetes in the juvenile who is an unstable, ever-changing, growing individual. A discrepancy from complete control is countenanced by most clinicians as inevitable. As shown by postmortem statistics of Root and

the clinical results of Boyd and Jackson, control of the diabetes, difficult as it may be, pays dividends in the postponing of vascular degeneration.

In clinics where the philosophy is at variance with control, the incidence of retinitis is reported as 100 percent in juvenile cases of long duration, whatever be the degree of control. This is as would be expected when correlated with the results of those practicing meticulous control of hyperglycemia and glycosuria.

It is probable that retinopathy will not undergo substantial reduction until a smoother, automatically acting insulin, in complete homeostatic relationship with the organisms, makes total 24-hour control of the diabetes possible without sharp flings from hyper to hypoglycemia and without intermittent phases of excessive fat mobilization. These fluctuations probably exist to some extent in the best controlled diabetic under the best methods presently available.

The mildest diabetic, one with a "touch," frequently suffers from the most severe retinopathy. He is usually the neglected diabetic whose underlying disease is discovered by his alert ophthalmologist.

Effective treatment of diabetic retinopathy is essentially prophylactic and must take place in the early stages of the disease. It represents the most meticulous control of the hyperglycemia that is possible. The youthful and the adult diabetic in early stages of the disease should be treated vigorously by diet and insulin. The obese adult with beginning diabetes should have consistent, unrelenting weight reduction to improve insulin efficiency and carbohydrate metabolism. This vigorous treatment should not be applied to the elderly diabetic with advanced retinopathy.

When retinopathy has developed in the

late diabetic, the diabetic state must be sacrificed to the welfare of the eyes in order to avoid vascular catastrophe. A balanced diet, relatively high in protein for repair and maintenance of damaged tissues, a diet not calculated to reduce weight except most slowly and cautiously, and a diet that does not increase individual insulin sensitivity gives the best results.

Relative or absolute hyperglycemia must be cautiously avoided, since it causes, through compensatory adrenal response, rupture of fine fragile vessels and results in blindness. Meticulous chemical (sugar) control in these advanced patients becomes, therefore, meddlesome therapy.

At present, it would seem that few diabetics are well enough controlled to be promised freedom from eye complications. After 15 years of the disease, whatever be the age of the patient, the process is, at best, only delayed.

The evidence that diabetic retinopathy, as well as the underlying diabetes, is caused by a third and unknown condition is meager. It is likely that when the ideal, automatically acting insulin is discovered the incidence of diabetic retinopathy will approach that of a cross-section of the population for the same age grouping.

Discussion. Dr. Isadore Givner said that Dr. Anderson's emphasis on the importance of better diabetic control in slowing the development of diabetic retinopathy is most important. This has been the experience of others, including Rabinowich who stated that better dietary control may forestall retinal changes.

Joslin has emphasized, however, that the mechanism by which lack of control can affect the retinal vessels which induce hemorrhages is still a mystery. Yet here lies the crux of the situation for, if this factor could be established, methods of treatment might vary accordingly. Some say it is the hyperglycemia itself. This idea was championed by Graefe who stated that without increase in blood sugar no sign of diabetes would occur. Others believe it is the intermediate products of metabolic change dependent upon impaired protein metabolism, hypercholesterol, and liver dysfunction.

Priscilla White called attention to Smith's work with menotoxin and suggested a like toxin acting in diabetes as a vascular poison. Acting on this suggestion, Dr. Givner said that he arranged with Dr. David Macht of Baltimore to study blood sera in patients with diabetes that had marked vitreous hemorrhages and advanced capillary fragility. A case of this type recently studied, however, showed no toxin as studied with this phytopharmacologic method.

Statistics, such as quoted from Priscilla White's patients, cannot be evaluated properly unless one knows the duration of the diabetes. Duration of the disease has been emphasized by Dolger and others as more important than the severity of the disease or the control in the incidence of retinal pathology. Comparison of the figures given in Priscilla White's series of 850 eyes with Waite and Beethan's combined series of juvenile diabetics (where only 1.7 percent of the cases showed retinal hemorrhages) shows a marked discrepancy which can be explained only on the basis of the duration of the disease in White's cases.

In spite of Waite and Beethan's dictum that the only danger from insulin, insofar as retinal hemorrhages were concerned, lay in withholding it, Dr. Givner said he was inclined to agree with Dr. Anderson. He described a recent case in which an immediate acute attack of glaucoma was precipitated by the substitution of globin insulin, with its explosive action, for the protamine zinc that the patient had been taking with no ill effects.

In conclusion he emphasized Dr. Anderson's statement that, although diabetics show a greater incidence of increased capillary fragility at each decade than nondiabetic controls, a fragility which is especially marked in cases of diabetic retinopathy, the

present therapeutic approach (vitamin C, rutin, and high protein intake) is not a specific bulwark against vascular damage. We must continue our search for more effective treatment.

Viruses in relation to orbital neoplasms

Dr. Alson E. Braley said that the possibility of viruses causing neoplasms is a reasonably old hypothesis. The first of these investigations was carried out by Borral and others in France. The infectious etiology of neoplasms must meet rigid specifications in order to explain many facts.

Dr. Braley said that in November, 1947, Mrs. Alexander and he reported on a virus obtained from a patient with a neoplasticlike lesion in the orbit. The differential diagnosis of this tumor was rather difficult to make. The possibility of exophthalmos associated with a thyrotropic hormone may have been an exciting factor. After many biopsies the diagnosis of pseudotumor of the orbit was made. This virus may be one of the causes of pseudotumor of the orbit.

There does not seem to be any relationship between this virus and the etiology of Hodgkin's disease or lymphoma, even though a great deal of the existing pathologic processes found in the tumors produced by this virus are similar to lymphomas and Hodgkin's disease.

The association of hormonal disturbances such as have been reported by Weinstein, and Aprunt and McDearman, may have some influence on the development of these neoplasms.

Operation for blepharoptosis

Dr. Charles Littwin said that there have been about 80 procedures described for the correction of blepharoptosis, and he wished to present (with motion pictures) a report on the Trainor operation, which he felt was simple in its performance and efficient in its results.

He said that blepharoptosis is an abnormal drooping of the upper lid and may be divided into pseudoptosis and true ptosis. The former may be caused by an abnormal widening of the palpebral fissure on one side, thus producing an apparent ptosis on the other; or it may be due to disease or increased weight of the lid on the side of the ptosis, such as occurs with edema, elephantiasis, relaxed skin, prolapsed orbital fat, blepharochalasis, trachoma, tumors, endophthalmos, spasm of the orbicularis muscle, and neurofibromatosis.

True ptosis results from inadequate lifting power of the levator palpebrae muscle and is caused by an abnormality of the levator muscle or its nerve supply. It may be congenital, acquired, or hereditary in origin; unilateral or bilateral, partial or complete.

Dr. Littwin said that there are three main types of operations usually employed for the cure of ptosis: (1) Suspension of the upper lid from the brow, thus utilizing the action of the frontalis muscle for the lifting of the lid; (2) attachment of the upper lid to the superior rectus, thereby replacing the action of the levator by the lifting power of the superior rectus; (3) enhancement of the normal action of the levator by advancing, tucking, or resecting this muscle.

A successful operation for ptosis should meet the following requirements: (1) The curve of the margin of the upper lid should overlap the cornea equally on the two sides, covering the upper port of the cornea where the lashes are normally open; (2) the margin of the lid should be a smooth curve and similar in the two eyes, with no tendency to form a notch or Gothic arch or to invert the lashes when the lid is widely open; (3) the superior palpebral crease should correspond on the two sides; (4) the eye should be capable of being widely opened and of shutting completely, both in forceful closure and in sleep; (5) normal winking should be possible; (6) the vertical distance between the eyebrow and the margin of the upper

lid should normally be the same in the two eyes; (7) the upper lid of each eye should move synchronously with the globe in all directions of gaze; (8) diplopia or disturbing heterophoria should be absent.

It is doubtful whether any operation for ptosis ever completely achieved all these requirements, especially in a case of unilateral, complete, congenital ptosis. Certainly, the frontalis type of operation does not give this degree of perfection because the upper lid can be raised only by raising the brow. The superior rectus operation nearly always weakens this muscle, producing hypotropia and leaves the lower part of the cornea exposed in sleep. Adequate resection of the levator muscle in cases of complete congenital ptosis often produces lagophthalmos in downward gaze. Therefore, in any case of complete congenital ptosis the surgeon must decide which of these criteria are the most important and which should be ignored.

It is important to make an accurate diagnosis and then to choose an operation that will produce the best possible results in each case. In the case reported, Dr. Littwin said he chose the Trainor operation because there was everything to gain and nothing to lose. The upper rectus was not weakened as in the Motais operation and, if success were not obtained, the tarsal hammock could be undone, and the condition would be no worse than it was originally.

The technique of the Trainor operation consists of using a strip of the upper boarder of the tarsus as a hammock to support the upper lid by sliding it under the insertion of the superior rectus. The steps involved are:

1. Anesthesia. Four or five drops of 0.5-percent pontocaine are instilled into the conjunctival sac. (a) The lid is everted. The needle is thrust under the loose conjunctiva, just beyond the border of the tarsus and the solution is injected until the whole retro-tarsal fold balloons out. (b) The lid is righted, and without withdrawing the needle the point is pushed to the skin side and more

solution is injected to slightly balloon out the skin. Both surfaces of the entire lid thickness are completely anesthetized. An injection is also made in the belly of the superior rectus through the conjunctiva.

2. The lid is everted and held with fixation forceps. A cut is made in the upper border through the entire thickness about 2-mm. wide, and a strip of tarsus covered with conjunctiva, but not skin, about 15-mm. long is freed, leaving it attached to the inner end.

3. The superior rectus is grasped and a tunnel is made through Tenon's capsule under the muscle by means of a scissors point.

4. The strip of tarsus is then passed under the superior rectus, either with mosquito forceps or suture.

5. The free end of the strip is now attached to its original position with one or more sutures which are bitten deep in both tarsal body and strip.

6. A protective dressing, consisting of a broad strip of adhesive, is attached to the cheek, and the lower lid is raised so as to cover the cornea. Maintaining this traction upward, a piece of gauze is used to cover the upper lid and eyebrow. The adhesive is then attached to the forehead.

ECZEMATOUS KERATITIS AND ARIBOFLAVINOSIS

DR. H. J. STERN AND DR. J. LANDAU presented the paper on this subject, which was published in the AMERICAN JOURNAL OF OPHTHALMOLOGY, volume 31, page 1619, December, 1948.

Scientific program

Beta irradiation of the eye

Dr. William F. Hughes, Jr., presented the paper on this subject which was published in the American Journal of Ophthalmology, volume 32, page 351, March, 1949. A brief abstract follows.

Beta particles of radon represent a concentrated source of irradiation which is largely absorbed within the first 2 mm. of tissue and is therefore useful in the treatment of superficial conditions of the lid, the conjunctiva, cornea, and sclera.

The effective use of beta irradiation in ophthalmology depends upon an exact knowledge of the differential between the sensitivity of normal tissues and the pathologic tissues to be destroyed.

In general, lymphoid tissues (the follicles in vernal conjunctivitis), the epithelial growths (papillomas), and vascular endothelium (in corneal vascularization) form the most sensitive tissues which can be destroyed by beta irradiation without undue injury to the normal ocular structures.

Evaluation of loss of central vision and central scotomas

Dr. Helen Holt presented a paper on this subject. The discussion concerned the group of patients whose chief symptom was blurring or reduction of central vision with no history of associated ocular symptoms or known general illness which might have a bearing on the problem. The importance of an accurate history, evaluation of visual acuity with analysis of the manner in which the letters are read, age of the patient, and exact refraction was stressed. Central fields

were plotted on a tangent screen at a distance of 1,000 mm.

The central scotomas were grouped as positive and negative scotomas. The first type was considered as largely due to macular lesions, such as pathologic conditions of the macula, macular degeneration, macular hole, and infectious processes. The second type was due to lesions of the conducting neuron, the result of inflammatory, mechanical, vascular, or toxic processes, vitamin deficiencies, or hereditary degenerative conditions. Case histories illustrative of the various conditions with central field and fundus photographs were presented.

Discussion. Dr. Derrick Vail felt that Dr. Holt had presented a splendid dissertation on a subject which tends to be neglected in the modern practice of ophthalmology. Perhaps not as many of us take fields as should. Dr. Holt has pointed out the importance of this procedure, which can be time consuming but also rewarding for both patient and ophthalmologist. Particularly interesting is her discussion of patients "spotting" from one letter to another, particularly the subtle changes one may pick up unconsciously in testing the patient's distant vision. For some time he had noted that patients with negative scotoma can read charts better when the chart is not illuminated. These patients with a relative central scotoma will see the letters better than when the chart is lighted; whereas, in positive scotoma, such as central angiospasm, they will read 20/20 with the lighted chart and with the unlighted chart 20/50. Has Dr. Holt noted that?

Antistine in ophthalmology

Dr. Paul Hurwitz presented this subject. An abstract of the paper, which was published in the American Journal of Ophthalmology, volume 31, page 1409, November, 1948, follows.

The antihistaminic chemical drugs and their action were briefly reviewed and 50 cases of ocular allergy and their response,

symptomatically and therapeutically, to the new antihistaminic ophthalmic solution were presented. Antistine ophthalmic solution (Ciba) was advocated for use in the symptomatic relief of patients with extraocular allergy.

Discussion. Dr. Louis Bothman said that when he read Dr. Hurwitz's paper he feared that he was rather too enthusiastic. The report of 84-percent good results is pretty high. His own experience with these drugs in allergic conditions was not sufficient to permit definite conclusions. With pyribenzamine in solution, the patients complained of burning and he was reluctant to use it because of the irritating effect. Dr. Hurwitz's observation that the astringent effect reduced the injection was one of the outstanding findings, and relief from itching was the principal result. Dr. Hurwitz also noted improvement in folliculosis, but he had found no change in folliculosis with any of the antihistamine drugs, although there was some relief from itching and tearing.

The patients with marked injection seemed to get more relief with privine hydrochloride. With 0.1-percent solution they get sensitivity, and say it gives relief for 4 to 6 hours. He had seen no allergic manifestations with the use of privine. It constricts the blood vessels and acts almost immediately. He hoped to give antistine a more extensive trial to see what it would do.

With pyribenzamine in ointment and solutions, some patients had relief from itching, but some complained of burning and refused to continue its use. About all that can be hoped for is symptomatic relief, and apparently no drug will affect the folliculosis.

Dr. Hurwitz mentioned that he had not obtained results in cases of vernal catarrh. He, himself, had seen one boy who had granulations so severe that they produced severe keratitis. After two courses of radium the involved conjunctiva was removed, and the fornix conjunctiva was transplanted to the upper lid. Then follicles began to appear in the transplanted conjunctiva. After a period of 8 to 10 months of desensitization (during which radium and other treatment had been of no value), the granulations began to shrink and the conjunctiva in one eye became smooth. Even in this very severe form the condition is reversible. Whether this result was because of treatment of the mold sensitivity was not clear. This work should be continued, and this and other drugs should be used in the effort to relieve the patients.

Dr. Stefan Van Wein asked whether Dr. Hurwitz had noted any exacerbation of manifestations in the eye during the allergic tests.

Dr. Paul Hurwitz (in closing) said that possibly his percentages were a little high, as Dr. Bothman said. Individuals doing investigative work are sometimes carried away by their own enthusiasm. However, the director of the Ciba Laboratories has said that scattered reports from different areas of the country showed a 77 percent improvement in ocular allergic conditions with the use of antistine opthalmic solution.

With regard to the burning effect of antistine, it has been noted that it is not as severe as with pyribenzamine solution. It is usually fleeting. Only one patient refused to use the solution because of the burning; a small group complained but continued to use it. The majority of patients came back for more of the solution. This indicates that they prefer the burning to the itching that is present in ocular allergies.

In reply to Dr. Van Wein, he had noted no exacerbation of the ocular lesions during the skin tests.

CLINICAL MEETING

(Presented by staff members, Department of Ophthalmology, University of Chicago.)

CONGENITAL ECTOPIC PUPILS

Dr. Ryerson presented R. F., a 32-year-old white man, who came to the eye clinic

of The University of Chicago, July 23, 1947, with the complaint of inflammation of the right eye for the preceding two weeks. He gave the history of having had an operation on his left eye seven years previously in hopes of improving his vision. His uncorrected vision was: R.E., 20/100; L.E., 4/200. Examination revealed bilateral ectopic pupils. The right pupil measured 2 by 3 mm. and was displaced nasally. The left pupil measured 1.5 by 2.5 mm. and was displaced superiorly. There was a 1.5 by 3.0 mm. artificial pupil slightly below the axis of the left eye. The right eye was mildly inflamed and there was a 2+ aqueous ray.

The iritis responded well to atropine and conservative therapy. Because of his poor dental hygiene, he was referred to the dental clinic. He was treated for severe pyorrhea and several carious teeth were extracted.

The diagnostic tests were: Kahn, negative; urinalysis, negative: W.B.C., Hgb., and R.B.C., normal. Chest microfilm, negative. Old tuberculin skin test negative.

After the iritis in the right eye had cleared up a manifest refraction yielded the following correction: R.E., −0.62D. sph. $\subset$ +2.5D. cyl. ax. 135° gave the patient 20/40 vision. It was not possible to improve the vision of the left eye. The patient habitually squinted to see clearly and preferred this to a glass prescription. He was successfully employed as a painter.

Gonioscopic examination revealed many peripheral anterior synechias, especially inferiorly. The lenses did not appear to be ectopic.

B. F., aged 15 years, a sister of the patient, presented herself primarily for our benefit. Her uncorrected vision was: R.E., 20/100; L.E., 5/200. Her right pupil was displaced toward the 10-o'clock position and the left pupil toward the 12-o'clock position. The pupils dilated poorly with homatropine, paradrine, and neosynephrin. It was not possible to improve her vision on a manifest refraction.

Slitlamp examination revealed bilateral cataractous lenses consisting mainly of peripheral punctate opacities. In the left eye, there was a beautiful display of zonular fibers. There was a slight irregularity of the equatorial portion of the left lens.

The original patient (R. F.) has children, aged 3 and 5 years, who have no apparent ocular defects.

NUCLEAR APLASIA AND MARCUS GUNN PHENOMENON

DR. STEPHEN J. ALEXANDER presented the case of J. C., a 4½-year-old white boy of Polish parentage, who was first seen at the University of Chicago Clinics, January 12, 1948. The mother of the child stated that since birth the right eye seemed smaller, it did not move, and the upper lid drooped.

Past history. No serious infectious diseases, no injuries or other defects were present. The patient was the third child born. Pregnancy, labor, and delivery were normal.

Family history. The father and paternal grandfather have some type of neuromuscular anomaly. The mother has a questionable left ptosis and a high exophoria. One older sister is living and well; one younger sister is living and well; one older sister died shortly after birth of "enlarged thymies."

Physical examination. Vision was: R.E., 10/30, not correctible; L.E., 10/20, with correction, 10/30. The facies were asymmetrical, the left side of face was most prominent. The right palpebral fissure was narrower than the left. Examination of the extraocular muscles revealed a right ptosis, partial paralysis of the right third nerve, complete paralysis of the right fourth and sixth nerves, and a Marcus Gunn jaw-winking phenomenon.

On convergence the right eye turned in less than 10 degrees and there was no movement in any other direction of gaze. The pupils reacted normally. The anterior segments and fundi were normal.

The patient is wearing the following pre-

scription: R.E., −0.75D. sph. ⊃ +3.25D. cyl. ax. 105°; L.E., −0.25D. sph. ⊃ +2.25D. cyl. ax. 92°.

Dr. Douglas N. Buchanan of the department of neuro-pediatrics confirmed the above diagnosis.

SARCOID UVEITIS

DR. A. W. FELDMAN presented Mrs. B., a 59-year-old white woman, who first came to the eye clinic of The University of Chicago with a number of minor complaints and the significant complaint of moving black spots. Her past history revealed that she had been discovered to have diabetes one year previously. Her corrected vision was: R.E., 20/40; L.E., 20/25. The eye was somewhat injected but the patient had a mild bilateral conjunctivitis at the time. The media of the right eye were slightly hazy. Slitlamp examination of the eye revealed numerous mutton-fat keratitic precipitates and a 1+ aqueous ray. The patient was started on 5-percent homatropine and later switched to atropine. On one occasion, a few small perivascular exudates were seen near the macula.

The patient had all her mandibular teeth extracted on the recommendation of the dental clinic because of a nonsuppurative periodontitis. The metabolism clinic has easily controlled her diabetes with moderate dosage of insulin and diet.

Because of a peculiar dilatation of the vessels of the nose, the patient was referred to dermatology. A tentative diagnosis of lupus pernio was made. This was later confirmed, as a biopsy of the nose revealed sarcoidosis. The dermatologists instituted calciferol therapy (high vitamin D). Shortly thereafter, the nose became quite painful and a crusted lesion developed. This cleared up when the calciferol was stopped. X-ray studies of the hands and feet and of the chest did not reveal evidence of sarcoidosis.

The vision of the right eye dropped to hand movements at two feet and at times the eye was quite painful. Atropine therapy had to be discontinued because the patient became sensitive to atropine. A secondary cataract developed and there was some deep vascularization of the cornea. The left eye remained essentially normal.

The following diagnostic and laboratory tests were performed: Old tuberculin, 1:10,000 and 1:1,000, negative; W.B.C., 10,800; Hgb., 16.2 gm.; R.B.C., 5.28 million; sedimentation, 27 mm.; urine, usually negative; highest fasting blood sugar, 115 mg. percent; serum calcium, av. 10 mg. percent; serum phosphorus, 3.8 mg. percent; alkaline phosphatase, 2.4 units. Plasma proteins: Albumin, 4.70 mg. percent; globulin, 2.54; A/G ratio, 1.85. Petechial count, 11 (Thompson).

This case is somewhat unusual from the following standpoints: (1) Although the general pathologic processes associated with sarcoid uveitis are spotty, they are usually located in the lungs and lymph glands. The lesion responsible for diagnosis in this case was located in the skin; (2) sarcoid uveitis is usually painless, but in this case there was considerable associated pain, although there was no evidence of secondary glaucoma; (3) sarcoid uveitis is bilateral in the majority of cases but was unilateral in this case.

SALZMANN'S CORNEAL NODULAR DYSTROPHY

DR. P. G. WOLFF presented Mr. J. A. H., a 58-year-old machinist, who was first seen in the eye clinic of The University of Chicago on February 21, 1944, complaining of sudden loss of vision in the left eye, following the extraction of 10 teeth, about 6 weeks previously. Aided vision was: R.E., 3/200; L.E., 20/30, not improved by a 1-mm. pinhole. A thrombosis of a branch of the left superior temporal retinal vein was found. This gradually resolved and four months later vision of the left eye had improved to 20/20+.

A rather vague history of the cause of the poor vision in the right eye was the best that could be obtained. First, at the age of 8 years this eye was very irritated and painful at irregular intervals. No doctor was consulted

and this spontaneously ceased about two years later without any recurrence of either pain or other annoyances. By the age of 15 years vision in the right eye was already noticeably decreasing and it has continued its unrelenting, slow, steady decline ever since. All eye doctors that he had seen advised that there was nothing to be done.

The patient did not believe that any of his seven siblings, his parents, or other relatives had had any "eye trouble." There was no history of consanguinity.

General physical examination revealed a moderate hypertension, mild generalized osteo-arthritis, and a fused left hip. There were conflicting opinions as to the nature of the etiology of the last-mentioned condition, but the Crile Clinic in Cleveland told him it was "acid fast" about 30 years ago. In addition, X-ray examination revealed old healed apical lung lesions. Old tuberculin, in 1/1,000 dilutions, gave a negative skin test. Repeated blood findings, including the Kahn test, and urinalyses were negative.

Objective examination of the left eye was negative except for some thinning of the left cornea without any opacifications in the inferior temporal region and for moderately advanced arteriosclerotic vessel changes in the retina.

The right eye never showed evidence of irritation or infection during observation. The right cornea was of normal size and shape, measuring 11 by 10 mm., and, except for the elevation of the nodules, was of normal curvature. Its sensitivity was reduced about 50 percent.

The pathologic changes were in a horizontally oval pattern, extending the breadth of the cornea and measuring 5 mm. in the vertical diameter. This pattern consisted of 5 elevated, blue white, structureless, opaque nodules, clearly showing that they had been formed by the union of previously existing small nodules, all lying in the superficial stroma.

The posterior one half of the cornea was normal. This cornea had never taken a fluorescein stain. All about its margin and passing over the limbus could be seen many fine superficial blood vessels on their way to the nodules. The central and the peripheral superior and inferior portions show a diffuse superficial gray clouding through which the underlying structures could be seen to be of normal appearance. The pupil reacted promptly.

With the slitlamp there could be found no regular obstruction of the dystrophic nodules, although their centers were uniformly more elevated and white than the surrounding periphery. They were observed to extend forward some one-half the normal thickness of the cornea. The corneal nerves were observed as normal. One pupillary nodule prevented a fundus study but repeated peripheral and Bjerrum fields of this eye revealed nothing abnormal.

While under observation for the past four years, there has never been any irritation or inflammation in the right eye; there has been neither apparent advancement or the disease nor any evidence of involution. To date, no evidence of involvement of the left cornea can be seen.

Richard C. Gamble,
Secretary.

LOS ANGELES OPHTHALMOLOGICAL SOCIETY

Dr. Orwyn Ellis, *chairman*

SYMPOSIUM ON ORBITAL IMPLANTS

Dr. Clarence Albaugh stressed the criteria of a good implant.

1. Adequate blood supply to prevent slipping of the muscles from their attachment to the implant.

2. Avoidance of pressure on the conjunctiva.

3. Protection of the cul-de-sac.

4. Even weight distribution between the

muscles and the lower lid by a floating-type appliance over the implant. These criteria were satisfied by a new type of basket implant as devised by Dr. Albaugh. A motion picture clearly demonstrated these points.

DR. ORWYN ELLIS described his covered implant which has been used successfully by a number of men. The implant consists of a lucite ball with an anterior ring. In 80 cases in which the implant has been used for over 10 months there was only one instance of extrusion. Dr. Ellis stated that since Tenon's capsule and the conjunctiva are fused to the sclera for 1 mm. to 2 mm. around the limbus, removal of the globe cannot be replaced with more than an 18-mm. sphere. He demonstrated his implant by the use of slides.

DR. GEORGE KILGORE of San Diego (by invitation) reported on the work at Dibble Hospital during the war. He found that the Cutler basket implant gave poor results, perhaps from faulty technique, and that it was frequently extruded. It was given up because of the atrophy above and behind the implant, and the Cutler doorknob implant was used. Good results were seen in some cases with the doorknob type but extrusion also occurred. He described three cases in which the doorknob implants were used.

1. The medial rectus pulled from its attachment postoperatively and could not be reattached, so it was removed and a basket implant was substituted.

2. A doorknob implant was placed successfully for two weeks and then the medial rectus pulled loose. A basket type was tried but was extruded because of infection but was later successfully placed.

3. Ideal movement was noted but the eye chattered when the patient read because the pin was too loose in the implant. Convergence was good as well as the vertical and lateral movements.

The important points to consider, according to Dr. Kilgore, are:

1. An additional pursestring suture through Tenon's capsule and the conjunctiva to take the strain off the muscles and allow them to heal well.

2. The medial rectus will tear loose if the good eye is uncovered too soon.

3. Penicillin and sulfa drugs should be used to keep down any infection and allow better healing.

4. Lag of movement seen with the basket type can be prevented by the doorknob implant.

DR. GEORGE LANDEGGER stated that the most important thing in an implant was permanency and that an implant covered with conjunctiva was best. Good movement in the extremes of rotation were not necessary. The larger size implants were favored since some of Tenon's capsule was gained from that stripped off the muscles. He favored the Ellis implant, having used it successfully in 7 cases. In one case, however, the implant was extruded from an inflamed orbit.

DR. GILBERT STRUBLE said that the buried implant always has a lag in movement and cannot make the excellent appearance of the Cutler and Ruedemann types. He used the 24-mm. size, earlier type Ruedemann implant in over 20 cases but all were failures since strabismus developed in all the patients when the backs of the prosthesis moved postoperatively. Sensitivity to the acrylic of the implant caused great thickening of Tenon's capsule and eventual extrusion of the eye.

The more recent mesh-type Ruedemann implant had not been observed by Dr. Struble. He had to remove three of the Cutler ball and ring implants because of recurrent cellulitis, and these were successfully replaced with glass balls. He felt that the Cutler basket implant gave a poor appearance because of the depression of the sulcus of the upper lid. Bone balls were condemned since draining sinuses were produced and the fragments of bone were so hard to remove.

Dr. Struble has gone back to using the old type of transplants since he felt there was a violation of general surgical principles in trying to attach muscles to nonviable tissue. The ideal volume size to be replaced by the implant was 18 to 19 mm. The muscles were not drawn over the implant since they were of no added help. A pressure bandage was applied for a week.

Dr. George Zugsmith favored an implant of the Ellis type which has complete covering of the implant by the conjunctiva. He felt that eviscerations with scleral implants gave the best results and believed that this was the best operation in all cases except sympathetic ophthalmitis, tumors, and in old and debilitated patients where an implant wouldn't be used anyway.

Mr. Ted Kaiser (by invitation) discussed prostheses as related to the type of implant. He said the implant will not move more than the cul-de-sac and that subse-

quent shrinkage which occurs after surgery accounts for the limitations. The appearance was best in eviscerations with scleral implants. Some basket implants pull the conjunctiva forward into the basket and thus foreshorten the socket and give a poor fit. Sewing up the posterior rent in Tenon's capsule after enucleation, as advocated by Dr. Rodman Irvine, has given good support since it brought the implant farther forward.

Dr. Abraham also emphasized the value of a large cul-de-sac to allow full movement of the implant and thus explained why eviscerations seemed to have better movement.

Dr. Loutfallah stressed the technique of a careful enucleation and the use of the obliques to hold the eye forward. He mentioned the new AO implant which combines the Cutler and Ruedemann principles.

Daniel B. Esterly,
Secretary.

Ophthalmic Miniature

I am very sincerely solicitious for the preservation or curing of Mr. Langton's sight, and am glad that the chirurgeon at Coventry gives him so much hope. Mr. Sharpe is of opinion that the tedious maturation of the cataract is a vulgar error, and that it may be removed as soon as it is formed. This notion deserves to be considered; I doubt whether it be universally true; but if it be true in some cases, and those cases can be distinguished, it may save a long and uncomfortable delay.

Boswell's Johnson, letter to Bennet Langton, October 18, 1760.

AMERICAN JOURNAL OF OPHTHALMOLOGY

Published Monthly by the Ophthalmic Publishing Company

THE NEWLY BLINDED

The ophthalmologist's responsibility to his newly blinded patient should not cease at the termination of his professional services. The losing battle to save sight is a hard and difficult one, encompassed by physical and emotional distress on the part of the patient and much soul-searching, mental anguish on the part of the surgeon, who dies a little every time one of his patients becomes hopelessly blind. There is little comfort here in the words of Hippocrates, "The art is long, life is short, experiment perilous, decision difficult."

The honest struggle to do everything possible and to see to it that everything possible is done for the patient usually ends up with the patient being grateful to his physician for his care, even if futile, and the latter filled with respect and admiration for the patient's fortitude in adversity. The terrible fight has engendered a mutual regard and friendship that deserves cultivation.

Many new and good things in the training of the newly blinded came out of the experience of the last war, especially from the program established by the Army at Old Farms, Avon, Connecticut. These new techniques

716

and methods of approach to the problem have been carried on and applied to the civilian needs, not as yet, however, to the fullest possible extent. The keynote of the modern philosophy in this field is that of instilling and fostering self respect in the afflicted individual. The training is long, often seemingly brutal, generally agonizing, frequently affected by setbacks, but to be successful always honest and frank. Experience has shown that the sooner the newly blinded person starts on learning how to be blind the better. ·

In a recent pamphlet, *The Newly Blinded*, printed for distribution by the Seeing Eye, Inc., Morristown, New Jersey, there is this statement that sums up the situation. "If newly blinded men and women are approached and looked upon as normal human beings; if they are given sympathetic understanding rather than maudlin sentimentality; if an effort is made to assure them that they still have their rightful place in the family and the community; and if they are encouraged to lead active lives in spite of blindness; then a true service will have been rendered not only to them but to their families and to the Nation."

The ophthalmologist is the last line of defense against blindness. He should be the first line of offense against the depression and gloom that envelop it. His fitness for this task depends upon his training and wisdom. It is his stern duty to exert his capacity as wise physician, friend, and counsellor. It is an integral part of his responsibility to his patient. It is not to be yielded up until the blind person is properly guided into the new career and terrifying experience of blind living in a seeing world.

In order properly to discharge this responsibility, the ophthalmologist should know much about the new techniques. He should know to what proper agencies in his community he can direct his charge. Most of these agencies are good and noble, others less so. He should be familiar with the Talking Book, the Braille watch, the writing guides,

the Seeing Dog, and all of the other auxiliary things and services that splendid and generous people have made available.

A small but most important aid in this first approach is the pamphlet, *The Newly Blinded*, already referred to. It is brief and austere, worthy of the beauty of its philosophy of help and of its great service to the patient and his family. The paragraphs on orientation, walking, personal appearance, table etiquette, smoking, Braille, the Talking Book, watches, handwriting, typewriter, recreation, theatre and movies, family, and employment are short but adequate. They were written by blind men out of their experience.

The Seeing Eye, Inc., of Morristown, New Jersey, will supply physicians and the personnel of hospitals with copies of this manual upon request. Each ophthalmologist should have a few on hand against the need.

Derrick Vail.

PONTOCAINE ALLERGY: TECHNIQUE OF INSTILLATION

On page 263 of the February issue of the JOURNAL, Thomas W. Cowan reports a striking case of allergy to pontocaine, manifested by redness, swelling, and itching of the skin of the lids after removal of a chalazion. The patient subsequently gave a rather violent reaction to a patch test on the arm.

The author's description of the technique of anesthesia in this case suggests certain comments on the customary routine employed for instillations not only of pontocaine but of other drugs. From observation of instillation as practiced in a number of hospitals, clinics, and offices, by surgeons and nurses, I am disposed to believe that this apparently minor field of daily technique may be open to general improvement.

Allergic reactions do not always depend upon the amount of offending substance involved. But sometimes they do, and it is better not to employ more of a drug than is necessary for the effect desired. It is also to be noted that the cornea and conjunctiva

sometimes appear to be less sensitive to a given drug than is the surrounding skin. This is true of atropine, which may produce an annoying skin reaction but much less disturbance of the conjunctiva. However, some of this apparent difference in sensibility may be credited to the fact that the tears are constantly active in removal of instilled drugs, while the skin has no such protection.

The eye itself is capable of absorbing only a very small quantity of the instilled solution, from the thin film of the drug which spreads over the conjunctiva and cornea. Moreover, under ordinary circumstances, out of the much larger quantity ordinarily dropped on to the eye at one application, only the amount of a single small drop remains in contact with the eyeball, the remainder being promptly spilled over the lid margin.

(It may be worth while to mention here, especially as bearing on the mixing of small quantities of dilutions, that the drop from a medicine dropper whose tip has an inside caliber of 2 mm. is not a minim but only about three fifths of a minim.)

Thus, of the "two or three drops" (rather frequently much more) dropped upon the eye by an assistant or nurse, most of the drug stays on the skin of the face, without surgical benefit, but always capable of irritating the skin. For ordinary purposes, no more than one drop of 0.5 percent pontocaine is necessary, if properly instilled. This is plenty for removal of a superficial foreign body from the cornea, although rather more is sometimes required for a foreign body close to the limbus. The cornea is usually insensitive as soon as the burning experienced by the patient from the instillation has ceased. The greatest efficiency is obtainable by laying the last joint of the left thumb flat on the upper lid and brow while the patient looks down, sliding the lid and brow up on to the forehead, with gentle but uniform pressure, and then placing the single drop on the sclera above the cornea—not allowing the drop to fall from a rather considerable height.

In using instilled pontocaine as a preliminary to infiltration, I have not found it necessary to make more than one such preliminary instillation. In advising the mother how to instill atropine in a young child, prior to refractive estimation. I emphasize that at each instillation only sufficient solution to make a single drop should be drawn into the dropper.

Some evidence of allergy to pontocaine has been experienced by me on a few occasions after repeated use of 0.5-percent solution of pontocaine, in connection with the permission rarely given to a workman to employ such a solution in carrying on important work after burn from a welding arc, or other minor injury. Special interest attaches to Cowan's case, on account of the severe reaction and the apparent complete lack of previous use of the drug.

W. H. Crisp.

SURGICAL TREATMENT OF HETEROTROPIA

The best method of surgical treatment for noncomitant heterotropia has long been a subject of controversy. As has happened in so many other controversies, two schools of thought have arisen. One school favors a direct attack on the paretic muscle by the performance of one of the strengthening operations. The opposite school prefers an attack on the direct antagonist of the paretic muscle by some one of the so-called weakening operations.

The latter school owed its existence almost solely to the frequent and often rather remarkable "recoveries" of paretic muscles when the opposition of their direct antagonist was purposely decreased.

The explanation generally accepted has been that a paretic muscle, when antagonized by a normal muscle, never had the chance to regain normal tonus even after the original cause of the paresis had ceased to exist; presumably the once paretic muscle was put on such a stretch due to partially unopposed ac-

tion of the antagonist that it failed to function normally while the antagonist meanwhile became spastic and thus continued its dominant role even after the cause for the paresis had disappeared. Proponents of the "weakening operation" could thus point to a fairly satisfactory percentage of surgical "cures." Their explanation for these satisfactory results was always suspect and lacking in real proof.

Those favoring a direct attack on a paretic muscle objected to any weakening operation on quite logical grounds. The mere fact that one muscle is weak is a poor excuse for weakening another and trying to strike a balance in the degree of weakness, as it were. The school favoring the strengthening operation for paretic muscles can also point to a respectable percentage of surgical "cures."

Both schools explained their failures by saying that the paretic muscle was just "too weak." The "weakening" school believed that the paretic muscle was too weak to regain any tonus and then resorted to some "strengthening" operation as a second procedure. Those in the "strengthening" school state that it is perfectly obvious that shortening a completely paretic muscle will not enhance its effect in the slightest except, perhaps, as an anchor.

There the discussion comes to an end with no satisfactory decision in favor of either side.

It must be said that the "strengthening" school apparently had a better explanation for their failures than did the "weakening" school. Since each school is able to present a fair percentage of successful cases, it would be highly significant if the failures could be explained on some logical grounds. It would seem that perhaps the failures of one school may be the successes of the other and vice versa. If cases could be properly classified prior to surgery, then the proper mode of attack—strengthening or weakening—would be clear and the general batting average of both schools might rise to far more satisfactory and impressive heights.

Some light is thrown on the subject by always using the phrase "apparently paretic" instead of just "paretic." The idea of apparent paresis rather than real paresis opens a new line of thought. What would cause a muscle to appear to be paretic when actually it is not—or at least was not originally?

If one muscle appears to be paretic and yet is found upon investigation to be normal, attention is then logically turned to the antagonist. The muscles of each eye work in antagonistic pairs. When the agonist contracts, the antagonist must relax and vice versa, according to Sherrington. Most of our thought has been directed at only one half of this problem; namely, that of contraction. If a muscle contracted properly, it was considered to be normal; if not, it was subnormal and therefore paretic.

The other phase—that of relaxation—has seldom been considered except in the same breath with "spasm." Spasm is a nice idea on paper, but even Duane had doubts about it as an individual entity.

Thinking through the relaxation phase of the problem, anyone will readily admit that, if an antagonist is prevented from proper relaxation by any reason whatsoever, the agonist will be prevented from securing the maximum effect from its contraction and will, therefore, appear to be weak or paretic. This would account for an appearance of paresis where no paresis, in the true sense of the word, exists. The important question, then, becomes: "What will prevent a muscle from proper relaxation when its antagonist contracts?"

Recent studies have suggested that many apparently insignificant anatomic anomalies associated with the ocular muscles or their fascial connections, while not preventing in any way the contraction of those muscles or enhancing their mechanical advantage at all, will nevertheless often serve to prevent adequate relaxation of those same muscles during the contraction of their antagonists. This can be easily proved by anyone willing to try the forced duction test.

For example, there is left esotropia and the left lateral rectus appears to be paretic; if, under general anesthesia, one attempts forced abduction of the left eye by depressing a muscle hook in the lateral conjunctival fornix, any resistance to this forced duction can be felt easily via the muscle hook and may even produce noticeable retraction of that eye. If there is only paresis and nothing else, there should be no resistance to forced abduction; there is no such resistance in normal eyes.

On the other hand, any cause acting to prevent adequate relaxation of the medial rectus will serve to produce resistance to the forced abduction. When such resistance to the forced duction test is encountered, surgical exploration of the offending medial rectus will quickly reveal whether the obstacle to adequate relaxation is due to contracture and perhaps fibrosis of the muscle alone or to some anatomic anomaly or to a combination of both.

Frequently, in young patients the muscle in question will be found to be normally elastic and forced abduction of the eye becomes free and easy only when the associated anatomic anomalies are sectioned. Once adequate relaxation is assured in the medial rectus, the lateral rectus can then contract fully and is obviously no longer paretic.

Here is an explanation for the successes of the "weakening" school and for the sometimes remarkable "recovery of tonus" of a "paretic" muscle.

If these same anomalies are not sought, found, and sectioned, they also explain the failures of the "strengthening" school; no matter how much "strengthening" one performs on an apparently paretic muscle, if the fault lies in its antagonist, the "strengthening" procedure is going to be of little or no avail.

It is perfectly logical to attempt to strengthen a truly paretic muscle. It is com-pletely illogical to direct our fire at a muscle that is "apparently paretic" when in truth the fault lies in the antagonist.

What has been called the "weakening" school is in reality not that at all. It should more accurately be called the school of "removing obstructions to proper relaxation." Removal of such obstacles on an antagonist allows an agonist to contract fully and efficiently and thus to appear to gain strength. The weakening school is really a strengthening school after all. The weakening school gained a majority of their successes in cases of "apparent paresis" while the strengthening school gained theirs in "true paresis."

When secondary changes of contracture and fibrosis have occurred as a result of inadequate relaxation over long periods of time, the two schools step on common ground although many adherents of both refuse to admit it. It would seem that the two schools arose because of a lack of knowledge of the true situation.

As more and more facts are brought to light, it is inevitable that the two schools will lose their identity and merge into a single group of those who are treating causes rather than effects. There are definite indications for the "strengthening" operations and equally definite indications for the so-called "weakening" operations. Neither procedure alone will result in 100 percent of cures and there is no reason to expect that they should.

Richard G. Scobee.

BOOK REVIEWS

GENERAL CYTOLOGY. By E. D. P. De Robertis, W. W. Nowinski, and Francisco A. Saez. Philadelphia and London, W. B. Saunders Company, 1948. 345 pages, 143 figures, and index. Price, $5.50.

This book relates knowledge concerning the composition of the cell and, in particular, that knowledge which results from the

application of modern physical methods such as polarization optics, X-ray diffraction, the ultramiscroscope, and the electron microscope.

The authors are De Robertis, whose microphotographic records of the path of the poliomyelitis virus along the nerve fibers, made in the department of biology at the Massachusetts Institute of Technology, have been widely publicized; Nowinski of the department of anatomy at the University of Texas Medical School; and Saez of the Institute of Montevideo.

From the first chapter, which presents the history of cytologic knowledge from the discovery of the cell to the new theories of interpretation of cellular structure, through the final chapter, which is on the differentiation, senescence, and death of the cell, the reader is aware that here is a book written by up-to-date authorities in the field of cytology.

Since it is impossible in a short review to discuss the entire text of a volume such as this, I should like to single out Chapter XI, "Visible Manifestations of Cellular Activity," as the one that may well arouse an unusual amount of interest.

In this chapter, ameboid motion is discussed as well as the property of chemotaxis which has great importance in the defense mechanisms of the organism and especially in inflammation, certain substances attracting or repelling cells and so influencing their motion.

Advances in the study of the ultrastructure of the cilia and flagella, and the resultant motion, are reviewed. With polarization optics the cilia and the flagella show a positive intrinsic and form birefringence, which leads to the belief that they are composed of submicroscopic fibrillas orientated along the length of the axis. Direct evidences of this ultrastructure have been obtained with the electron microscope.

Analysis of movement has been facilitated greatly by ultrarapid cinematomicrography which permits one to follow the various phases in the contraction of a cilium and to calculate the duration of each cycle. One recent theory of the mechanism of ciliary movement is on the basis of changes in water content, the two sides of a cilium being believed to differ in their capacity to absorb water in such a way that the increase in the number of water molecules on one side would cause the cilium to curve toward the opposite side.

The visible manifestations of the nutrition of the cell—as phagocytosis, inclusions, or paraplasm—are included in this chapter together with the cytomorphologic aspects of cellular secretion and techniques to study the process of secretion by vital observation (biomicroscopy). In addition, there are fascinating diagrams of the processes of secretion in thyroid and parathyroid glands on which De Robertis has done much original work.

One has but to thumb through this book to understand why it has aroused an unusual amount of interest. It contains a great number of electron micrographs and examples of other forms of microscopy and X-ray diffraction, which are among the finest such pictures ever published.

Interesting and stimulating to anyone who has ever examined a slide under a microscope, the book is particularly excellent for students of medicine and for pathologists, but actually valuable for all who, for the purposes of teaching or investigation, wish to have a general and inspired view of the modern aspects and present-day orientation of cytology.

S. Rodman Irvine.

MANUAL FOR THE OBJECTIVE EXAMINATION OF THE OCULAR MUSCLE BALANCE. By Beulah Cushman, M.D. Ann Arbor, Michigan, Edwards Brothers, Inc., 1949.

Lithoprinted, 72 pages, references. On sale at the University Bookstore, 434 East Huron Street, Chicago 11, Illinois. Price, $2.50.

Teachers and students of ophthalmology have long needed a manual of objective examination of the ocular muscle balance. Dr. Cushman has done a good job of it. There are 16 short chapters beginning with the examination of the ocular muscle balance and finishing with suggestions for the surgical correction of squint.

The chapters on amblyopia and its treatment, the near point of convergence, convergence excess and insufficiency, divergence excess and insufficiency, and the value of orthoptics are particularly noteworthy.

Thirty-six cases, chosen from Dr. Cushman's extensive experience, are described in outline detail at the end of the manual and are most instructive. The manual is not intended to supplant the more extensive treatises. It supplements them with an economy of words that is most helpful. It is recommended most heartily.

Derrick Vail.

Toxoplasmosis. A clinical, serological, and histopathological study with special reference to the eye manifestations. By C. D. Binkhorst, M.D. Leiden, Stenfert Kroese, 1948. 163 pages, 14 figures, 3 colored plates, bibliography. Price: Paper bound, $3.00; cloth bound, $3.75. (This book may be purchased from the publishers, Breestraat 14, Leiden, Holland.)

Toxoplasma in human tissues has been observed in nearly every country in the world since Laveran discovered toxoplasma protozoa in animals in 1900. In 1911, Jankû of Prague found protozoa in the eye of a hydrocephalic infant. In 1939, Wolf, Cowen, and Paige isolated protozoa from the brain of a child, aged 31 days. Sabin, in 1937, published a work on toxoplasma and since then has been one of the chief workers in this field.

As one of the agents responsible for granulomatous disease in the eye, notably chorioretinitis, toxoplasma has become of grave importance in the determination of the etiology of this disease. Unfortunately, the diagnostic tests that have so far been evolved are either untrustworthy, time consuming, and expensive, or are too difficult for the ordinary laboratory to undertake. The future promises a good deal, however, along this line.

The monograph by Binkhorst is well written and of value. The first part consists of a review of the literature, the epidemiology and properties of the etiologic agent, the diagnosis, ocular manifestations, and treatment. The second part consists of a description of the author's own cases (20) and his observations.

Two of his cases were examined histopathologically. In Case 1, there was a bilateral, chronic, necrotizing retinopathy, with toxoplasma in one of the eyes; the choroid was almost normal. In Case 2, there was one small retinal granuloma.

The question is discussed as to whether the ophthalmoscopic picture is characteristic of toxoplasmosis. Inactive fundus lesions are probably not to be distinguished from chorioretinal atrophy by other causes.

This contribution to our kowledge of toxoplasmosis in ocular disease is timely and welcome, and will help in putting this condition on a firmer basis in the consideration of its importance in chorioretinitis.

Derrick Vail.

ABSTRACT DEPARTMENT

Abstracts are classified under the divisions listed below. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

1. Anatomy, embryology, and comparative ophthalmology
2. General pathology, bacteriology, immunology
3. Vegetative physiology, biochemistry, pharmacology, toxicology
4. Physiologic optics, refraction, color vision
5. Diagnosis and therapy
6. Ocular motility
7. Conjunctiva, cornea, sclera
8. Uvea, sympathetic disease, aqueous
9. Glaucoma and ocular tension
10. Crystalline lens
11. Retina and vitreous
12. Optic nerve and chiasm
13. Neuro-ophthalmology
14. Eyeball, orbit, sinuses
15. Eyelids, lacrimal apparatus
16. Tumors
17. Injuries
18. Systemic disease and parasites
19. Congenital deformities, heredity
20. Hygiene, sociology, education, and history

1
ANATOMY, EMBRYOLOGY, AND COMPARATIVE OPHTHALMOLOGY

Ballantyne, A. J. The nerve fibre pattern of the human retina. Tr. Ophth. Soc. U. Kingdom 66:179-190, 1946.

The author reviews earlier work of others and describes the nerve fiber layer of the macular area and temporally. He presents an answer to the unsolved problems of what happens to the fibers of the papillomacular bundle at the margin of the macula and temporally to it and the extent and structure of the raphe. In his investigation the unstained retina was spread face upwards on a glass slide and mounted in glycerin. The composite picture showed that as the radial bundles pass from the disc they gradually spread out more thinly, exchanging fibers from one to the other and showing occasional interspaces. As the nerve fiber bundles approach the periphery they spread apart and the interspaces are wider and are occupied by the feet of Müller's supporting fibers. The raphe is an area from one-half to two millimeters wide within which the nerve fiber bundles assume the form of a network, the meshes of which are so irregular as to give no indication of the direction or destination of the fibers. The findings explain the form of some retinal lesions but do not reveal the relations of the nerve fibers to the ganglion cell and to other elements of the central area of the retina, nor do they provide an anatomical basis for the phenomenon of the nasal step. (10 figures.)   Beulah Cushman.

Loewenstein, A. Glomus cells in the human choroid. Nature 163:69, Jan. 8, 1949.

Large round or polyhedric cells of 10 to 20μ. in diameter are found in the periphery of some chorodial arteries in the posterior pole of many human eyes. They have clear protoplasm, and their nuclei are stained an even dark purple with hematoxylin without visible chromosomes or nucleoli. These so-called glomus or epitheloid muscle cells occur in groups in the media and adventitia of arteries in hypertension and other circulatory disturbance. They serve as cushions by filling the lumen of arteriovenous anastomoses and by shrinking or swelling they may open or close the arteries and veins. They make possible a short circuit from artery

to vein in many normal and morbid processes. It is also conceivable that they are contractile and, constricting certain vessels, help to regulate the choroidal blood circulation and intraocular pressure.　　　　　　　　R. Grunfeld.

Wolff, Eugene. **The mucocutaneous junction of the lid margin and the distribution of the tear fluid.** Tr. Ophth. Soc. U. Kingdom 66:291-307, 1946.

The author describes the junction between the skin and conjunctiva as a sharp line on a level with the posterior margin of the openings of the Meibomian glands, just where the lid margin is no longer wetted by the tears. This is confirmed microscopically. The eleiden and keratin layers of the skin end quite sharply and give place to several layers of nonkeratinized squamous epithelium. The number of layers of squamous cells are gradually reduced till at the subtarsal fold the superficial cells become columnar and cubical. In this region goblet cells begin to appear. The oily secretion of the Meibomian glands tends to limit the lacrimal fluid and acts as a low wall round the whole tear reservoir and directs the tears towards the puncta.

A strip of lacrimal fluid is found at the posterior margin of the upper and lower eyelids and the inferior marginal strip runs up on the cornea for a millimeter or so because of surface tension. It is prevented from overflowing by the secretion of the Meibomian glands. A tear lake was found at the outer canthus and the author emphasizes its importance because the lacrimal fluid from the upper conjunctiva may reach the lower conjunctival cul-de-sac through it. The puncta dip into the strips of fluid at the posterior lid margin and in this manner the lacrimal secretion reaches the efferent passages rather than by drainage from the lacus lacrimalis.

GENERAL PATHOLOGY, BACTERIOLOGY, IMMUNOLOGY

Dean Guelbenzu, Manuel. **Simple and effective therapy of ocular burns.** Arch. Soc. oftal. hispano-am. 8:1004-1015, Oct., 1948.

Because good results followed treatment of burns of the skin with powdered sodium bicarbonate, the author used it in burns about the eye and found it very satisfactory. He then tried an ointment of sodium bicarbonate in ocular burns, and found its effect very agreeable in acid burns, and of value in caustic burns. In the caustic burns he uses a 4-percent solution of ammonium chloride for the first two or three days, after which sodium bicarbonate was substituted. To explain its favorable action he refers briefly to the work on the physiology of inflammatory processes, by Elkinton, Wolff and Lee, Menkin, Schade, and Fenn and Evans. These investigators demonstrated that the increased permeability incident to an inflammation causes an invasion of the tissues by plasma and its proteins, with a consequent compression of the vessels, and cellular asphyxia. The inflammatory exudate upsets the local acid base equilibrium, with a shift toward acidity; the local anoxia leads to an accumulation of lactic acid, which rises from 19 to 240 percent. Associated with the local acidosis is a marked reduction in the bicarbonate and sodium anions, and an increase of potassium ions. The phagocytic activity requires an alkaline medium and is arrested in a medium with a pH of 5.5. The processes of cicatrization also require an alkaline medium, and are retarded in an acid medium. The beneficial effect of sodium bicarbonate is therefore attributed to its alkalinization of the tissues and normalization of the acid base equilibrium, to its effect on absorbtion of tissue fluids and local an-

oxia, and to its soothing local action on the inflamed tissue. (1 table.)

Friedenwald, J. S., Buschke, W., Crowell, J., and Hollaender, A. **Effects of ultraviolet irradiation on the corneal epithelium. II. Exposure to monochromatic radiation.** J. Cell. and Comp. Physiol. 32:161-174, Oct., 1948.

Experiments on the corneal epithelium of the rat are reported. In this paper the effects of monochromatic ultraviolet radiation of various lengths are noted. In a previous paper (1945) the results of an investigation of the cellular changes following the use of unscreened cold quartz mercury vapor arc were described. The stimulation of mitosis of the corneal epithelium in the cold quartz experiments of 1948 was found to be due to the gas, possibly ozone, that surrounded the generator. When ozone was removed from the exposed area by suction an inhibition of mitosis resulted. Mitosis inhibition, nuclear fragmentation, and loss of tissue cohesion in the corneal epithelium was observed after exposure to monochromatic ultraviolet radiation and sensitivity curves are described. F. M. Crage.

VEGETATIVE PHYSIOLOGY, BIO-CHEMISTRY, PHARMACOLOGY, TOXICOLOGY

Bakker, A. **Carbonic anhydrase and cataracta lentis.** Brit. J. Ophth., 32:910-912, Dec., 1948.

The author discusses the enzyme equilibrium of the lens. By lens culture he has studied the enzyme carbonic anhydrase. As the aqueous does not contain this enzyme, it seems probable that the lens produces its own carbonic anhydrase. The normal lens contains a high amount, lenses with some opacity have considerably less, and mature cataracts none. It was found that the concentration of car-bonic anhydrase decreased with an increase in cataractous changes.

von Brücke, H., Hellauer, H. F., and Umrath, K. **The relationship between the acetylcholine and aneurin content and the innervation of the cornea.** Ophthalmologica 117:19-35, Jan., 1949.

In 1938 von Brücke discovered the high acetylcholine content of the cornea which became greatly reduced after postganglionic section of the ophthalmic nerve. Now it is found that the epithelium contains nearly all the acetylcholine present in the cornea. After postganglionic section of the ophthalmic nerve, the acetylcholine content increases slightly during the first few hours and then starts to drop; if no keratitis sets in, it drops to about one-half normal. If a neuroparalytic keratitis follows, it varies inversely with the severity of the keratitis. The vitamin B_1 content of the cornea closely parallels the fluctuations in the acetylcholine content. Preganglionic section of the fifth nerve affects the acetylcholine and aneurin content of the cornea only slightly. Cocaine or pontocaine, applied topically, lower the acetylcholine content of the cornea. Topical application of acetylcholine in aqueous solution appears to be beneficial in neuroparalytic keratitis in man. The part played by acetylcholine in the metabolism of the cornea is not definitely known. Peter C. Kronfeld.

Duke-Elder, S., and Davson, H. **Studies on the intra-ocular fluids.** Brit. J. Ophth. 33:21-38, Jan., 1949.

In the cat and rabbit, the glucose concentrations in the aqueous humor and vitreous body are lower than would be expected on the basis of a simple diffusion equilibrium with the plasma. Experiments indicate that this deficit of glucose is due to the metabolism of both the lens

and the retina. The possible physiologic significance is discussed and the importance of including the vitreous body in any study of intraocular dynamics is stressed. Morris Kaplan.

Giardini, A. **The glucose content in normal and in diabetic persons.** Boll. d'ocul. 27:585-599, Sept., 1948.

Ninety-eight sugar determinations were performed in specimens of lacrymal fluid taken from 43 individuals with normal glucose metabolism and from 21 diabetics. The Hagedorn-Jensen method was used in spite of the fact that it measures not glucose alone but reducing substances. The results are shown in four tables. Normal tears had a glucose content of 0.02 to 0.28 percent; three subjects had reducing substances in their lacrimal fluid. Repeated examination on the same individual may reveal very different values. One of the diabetics had no reducing substances in his tears, the others 0.04 and 1.20 percent. The author did not succeed in obtaining phenylglucosazone crystals from the lacrimal specimens. Further research with the Nelson-Szomogyi method is contemplated. (Bibliography.) K. W. Ascher.

Grandjean, E., and Zwahlen, P. **Alterations of the ocular tension and of the retinal arterial pressure at high altitudes.** Helv. Physiol. et Pharm. Acta. 6:560-566, 1948.

During a stay at Jungfraujoch (3450 m.) the ocular tension and the brachial and retinal arterial pressure of five healthy subjects were measured daily. The tension dropped after several days at a high altitude which the authors attribute to a general dehydration of the organism. Whereas the brachial arterial pressure dropped at high altitude the retinal arterial pressure rose, which in the opinion of the authors is due to a peripheral vasodilation of the retinal vessels. This elevation seemingly reflects a parallel circulatory alteration of the cerebral vessels. R. Grunfeld.

Guimarães, Laertes. **Antibiotics in ophthalmology.** Arq. brasil. de oftal. 11:173-198, 1948.

This sixteen-page review of the literature regarding penicillin, tyrothricin, and streptomycin, to which is added a nine-page bibliography, should be of value to readers of the Portuguese language.
W. H. Crisp.

Herrmann, Heinz. **Effect of antihistamines on loss of adhesiveness of corneal epithelium after injection of histamine.** Proc. Soc. Exper. Biol. and Med. 69:506-507, Dec., 1948.

Histamine, injected into excised cornea, caused a marked decrease of epithelial adhesiveness. It effected the detachment of the upper layers of the epithelium from the basal ones. The corneas were incubated for 12 to 15 hours at 28 to 30°C. and the adhesiveness of the epithelium was tested with a simple scraper. It was possible to estimate adhesiveness approximately. If antihistamine was injected together with histamine, the anti-histamine protected the epithelium. Several antihistamines are compared quantitatively. R. Grunfeld.

Hoang-Xuan-Man, and Bailliart, J. **Benzyl-imidazol (priscol) in ophthalmology.** Ann. d'ocul. 181:702-723, Nov., 1948.

This drug is a sympatheticotonic peripheral vasodilator of low toxicity which has been employed during the past ten years in Raynaud's disease, angiitis obliterans, diabetic gangrene, arterial hypertension and other vascular degenerative diseases. It is used in tablets of 25 mg. for oral use, and in ampules of 10 mg. for retrobular injection. In 30 of 40 patients with macular senile and precapillary degenerations improvement

followed one to four injections. Either retrobulbar or oral administration may be employed, but their combined use is apparently more effective. In numerous other ocular degenerative vascular diseases the authors report improvement following the use of priscol.

Chas. A. Bahn.

Laborne Tavares, Cazimiro. **Antibiotics in ophthalmology.** Rev. brasil. de oftal. 7:53-67, Dec., 1948.

Penicillin, tyrothricin, streptomycin, chloromycetin, garlecin, and to some extent aureomycin are discussed as to forms of administration, and as to organisms against which they are respectively available. As far as possible, preliminary laboratory examination should be utilized to determine the responsible microörganism. Further clinical experimentation is desirable. (References.) W. H. Crisp.

Leopold, I. H., and Steele, W. H. **Choice of sulfonamide drugs for local use.** Arch. Ophth. 39:563-578, May, 1948.

Most striking of all factors that influence intraocular penetration of locally applied sulfonamide drugs is the state of the cornea. A great increase in penetration occurs when the cornea is inflamed and partially denuded. Theoretically, it is desirable to have a preparation of the same pH as the tears. If an ointment is desired an ideal vehicle is one that retards epithelial regeneration minimally, is of the oil-in-water type to enchance penetration, and maintain an alkaline pH as an aid in dissociation of the drug, and does not disappear too quickly from the conjunctival sac. Penetration is more rapid from solutions than from ointments. The sodium salt of sufacetimide (now available in 30 percent concentration) is the drug of choice, because of its low pH and great penetration. Sulfadiazine and sulfapyridine are next best.

Ralph W. Danielson.

McGraw, J. L. **Infection of the cornea due to herpes simplex.** Arch. Ophth. 40: 531-552, Nov., 1948.

After a general discussion of the nature of the virus and a review of the literature on treatment of herpes simplex, the authors describe their investigations. Penicillin is ineffective in combating the virus of herpes simplex in mice and in vitro. Streptomycin in high concentration seems to have a slight inhibitory effect on the virus in vivo. Tyrothricin in dilution of 33 mg. per hundred cc. has an unfavorable effect on herpetic infection of the eye of the rabbit. Hyperimmune serum and intravenous use of sodium iodide is ineffective. The local application of 3.5-percent iodine and 70-percent alcohol to herpes-infected eyes of rabbits delays healing and results in greater scarring. Anode iontophoresis of 0.25-percent zinc sulfate is contraindicated in dendritic kertitis in the rabbit but cauterization of dendritic ulcers with 20-percent zinc sulfate is of definite value.

Tschirren, B., and Wiesinger, K. **Investigations concerning the time element of the consensual pupillary reflexes at a high altitude.** Helv. Physiol. et Pharm. Acta 6:554-559, 1948.

The consensual pupillary reflexes of seven healthy men were examined at altitudes 550 m., 800 m., and 3450 m. above sea level. The average latent period is the same as in low altitudes and the average constriction time is considerably smaller in high altitudes. The daily average value of latent period and constriction time diminishes at the beginning of stay at high altitudes but increases after the fifth day. R. Grunfeld.

Verdaguer, J., and Sielacznik, A. **Use of chamico. (A Datura stramonium.)** Arch. chilenos de oft. 4:457-464, 1947.

This plant is a common weed among

the cultivated crops of Chile. Its pharmaceutical and toxic properties do not differ essentially from those of the Jimson weed of the United States. The author tabulates the results of tests upon the eyes of 550 patients with 12 mydriatics, including chamico, atropine, scopolamine, and homatropine. (References.)   W. H. Crisp.

Wiesinger, K., and Plüss, H. R. The size of the pupils in high altitudes. Part I. Examination with a photographic method. Helv. Physiol. et Pharm. Acta 6:528-539, 1948.

The size of the pupil of six persons was measured with a photographic method three times daily on 21 consecutive days at 800 and 3450 m. altitude. The diameter became gradually smaller at 800 m. and at an altitude of 3450 m. the pupils became extremely miotic between the third and fifth day and thereafter they gradually enlarged. The oscillations of the pupils, 1 to 2 minutes after illumination change, were smaller at 3450 m. than in the valley.

R. Grunfeld.

Wiesinger K., and Werner H. The size of the pupils in high altitudes. Part II. Examinations with a double-image pupillometer. Helv. Physiol. et Pharm. Acta 6:540-553, 1948.

The size of the pupils of ten persons was measured twice daily at 560 m. for 9 days, at 3450 m. for 9 days, and at 800 m. for 5 days. The apparatus used for the measurement of the horizontal pupillary diameter consisted of a double refracting Wollaston quartz prism. It was found that at high altitudes the pupils are constricted, the difference of size of the pupillary area in the morning and evening pupil is diminished and the oscillatory pupillary changes are smaller. Fatigue accentuates these findings. As the persons became adapted to the high

altitude, the altitude miosis disappeared altogether.   R. Grunfeld.

PHYSIOLOGIC OPTICS, REFRACTION, COLOR VISION

Barraquer Cerero, Tomás. Contact lenses and binocular vision. Arch. Soc. oftal. hispano-am. 8:981-987, Oct., 1948.

Barraquer reports the appearance of convergent strabismus in a high myope, for whom contact lenses were prescribed for cosmetic purposes. The patient wore minus nine spheres in each eye, which corrected the vision of the left eye to normal, and that of the right eye to 6/10. The right eye had a high degree of myopic astigmatism, the correction of which brought its vision to normal. The patient did not have binocular single vision, and used the left eye for monocular fixation. With normal vision in each eye the patient had simultaneous perception, but no fusion, and the right eye turned in. With orthoptic training binocular vision was developed, and the patient was enabled to wear the contact lenses with comfort.

Ray K. Daily.

Birren, J. E., Bick, M. W., and Fox, C. Age changes in the light threshold of the dark adapted eye. J. Gerontology 3:267-271, Oct., 1948.

Minimum light thresholds determined with the Hecht Shlaer adaptometer on 130 men between the ages of 18 and 83 years showed a significant decline in the subjects over 60 years of age and the most marked changes in those over 70. There was a larger range of individual difference in the older group. The technique is described in detail. The pupils of all subects over 40 were dilated with 5-percent euphthalmine in order to eliminate miosis. When violet light and white were both used there were similar changes found. There was no significant difference in dark adaptation between

subjects who lived in institutions and those who lived at home (2 tables).

Herman C. Weinberg.

Bischler, V. **Binocular triplopia.** Ophthalmologica 116:254-255, Oct.-Nov., 1948.

Postoperative triplopia is a bizarre visual phenomenon resulting from the simultaneous manifestation of anomalous and normal retinal correspondence in certain recently operated cases of squint, first described by Javal in 1864. With the recent developments in the field of binocular sensory co-operation in strabismus, triplopia has become well known. The author describes a typical case. Despite accurate surgical correction of the squint, triplopia has persisted for over a year, the anomalous correspondence maintaining its supremacy. Persistence of the two correspondences may be due to an actual obstacle to fusion which in the author's case was present in the form of a cyclophoria. Peter C. Kronfeld.

Campbell, D. A. **Primary amblyopia.** Tr. Ophth. Soc. U. Kingdom 66:413-428, 1946.

The author separates primary amblyopia from secondary amblyopia which is due to toxic, neurological, psychological and nutritional causes. An error of refraction, particularly anisometropia or bilateral hyperopia, is frequently the primary factor in the onset of suppressive amblyopia. Suppression follows a disturbance of the normal balance of position of the two eyes. The treatment of primary amblyopia should be begun as early as the age of six months by the use of atropine and glasses. Before the age of five years much less time was required to improve the vision than after that age. Longer periods of occlusion were necessary for those patients with vision of 6/60 or less. (5 tables.)

Beulah Cushman.

Cibis, P. **Contribution to the pathology of the adaptation of definite retinal areas. Part II.** Arch. f. Ophth. 148:216-257, 1948.

The author presents the theoretical background for the data he published in Arch. f. Ophth. 148:1-92, 1947 (abstract Am. J. Ophth. 31:638, 1948). The reader interested in the explanation of visual phenomena by photochemical processes will consult the iriginal paper. (235 references.) Ernst Schmerl.

Dartnall, H. J. A. **Visual purple and the photopic luminosity curve.** Brit. J. Ophth. 32:793-811, Nov., 1948.

The hypothesis that visual purple is the mediator of photopic luminosity sensations as well as of scotopic is investigated. Two main assumptions are made in developing the hypothesis. The first of these is that the production of visual purple from its precursors is a rapid process in comparison with regeneration from its photoproducts; the second, that the influence of absorption by the photoproducts on the light absorbed by visual purple is equal to that obtaining in a homogenous mixture of the substances.

It is shown that the effect of the accumulation of photoproducts (indicator yellow) in a retina exposed to light, is to move the position of maximum light absorption by visual purple towards the longer wavelengths. This process is not indefinitely prolonged. As the amount of indicator yellow accumulates the light absorbed curve of visual purple rapidly approximates to a limiting position having a maximum at about 550 mu. When this limiting curve is corrected for absorption by the ocular media and by the macular pigment, the resulting curve closely approximates to the photopic luminosity curve.

Apart from accounting for the Purkinje shift in a quantitative manner the hypothesis provides a basis for the explanation of a number of other visual phe-

nomena, notably the reduced sensitivity of photopic vision and the dependence of the rate of dark adaptation upon the previous light history of the retina.

Author's summary.

Evans, P. J. Amblyopia. Tr. Ophth. Soc. U. Kingdom, 66:397-412, 1946.

The amblyopia of congenital nystagmus is due to the movements of the eyes and the duration of fixation is the essential criterion of the level of visual acuity. The suppression is physiologic and not associated with the production of the impaired acuity, but is an essential adaptation to an altered visual mechanism. "Fusion" has little significance in the physiology of binocular vision. The grades of binocular vision are in fact grades of physiologic suppression in a center apart from the striate cortex. Suppression is a normal constant process. These grades account in progressive measures for normal vision, retinal rivalry, the suppression of alternating squint, congenital nystagmus, and amblyopia ex anopsia. (4 tables, 1 figure.)

Beulah Cushman.

Györffy, I., and Kahán, A. Hypersensitivity against contact-lenses. Orvosok Lapja 42:1337, Oct. 17, 1948.

Antistin-privin prolongs the time of tolerating contact lenses. This is ascribed to the hindering of the effects of histamine set free from the irritated cornea and conjunctiva. Gyula Lugossy.

Hamburger, F. A. The refraction of persons with normal vision. Klin. Monatsbl. f. Augenh. 113:261-266, 1948.

Organically normal eyes may vary in vision as a result of refraction, clarity of media, size of image, the size of cones, and better function of the individual cone. A statistical study of the refraction and vision of the normal eyes of 433 persons, 18 to 22 years of age, is presented. The vision varied from 6/4 to 6/7. An eye with 6/4 vision may have a 3/4-diopter astigmatism, whereas others with 6/8 may have only a small hyperopic error. Only 367 of the 866 eyes had spheric refraction alone. Almost a third had astigmatism of 0.50 diopters or more. A slight hyperopia is usual. Strict emetropia is the exception and such eyes have a myopia for blue light.

Max Hirschfelder.

Jonkers, G. H. Dark-adaptation measurements by two different methods. Ophthalmologica 116:350-356, Dec., 1948.

Recording of the corneoretinal potentials due to the opticokinetic nystagmus elicited by horizontally moving pattern of low light intensity can be used for objective adaptometry. In subjective adaptometry the appearance or disappearance of the light stimulus may be used as the criterion. The latter method was developed by Lohmann and seems to give the most accurate values although differences between the two methods are insignificant. Peter C. Kronfeld.

Kettesy, A. Pigment-anomaloscopy: a new procedure for testing the coloursense. Brit. J. Ophth. 33:47-54, Jan., 1949.

The author has devised an anomaloscope in which one can utilize pigment colors as well as spectral colors. The new instrument consists of a view box containing two cylinders around which are placed detachable papers bearing triangles or parallelograms of any color or shade of color. The subject looks through a slit and shifts the rotating cylinders on their axes until he feels that the colors match. (4 figures.) Morris Kaplan.

Kettesy, A. The stabilisation of the refraction and its role in the formation of ametropia. Brit, J. Ophth.33:39-47, Jan., 1949.

Steiger's doctrine of the origin of refraction is enlarged with the conception of stabilisation. The latter is the cessation of the growing of the eye, its term varies with individuals, and it is an inherited quality. The cause of the higher degrees of myopia is interpreted as retarded stabilisation. The two weak points of Steiger's doctrine, the excess and the asymmetry of the variation-curve, are explained by the biological peculiarities of stabilisation. Near work has nothing to do with the development of individual myopia, therefore restrictions in the near work of the young myopic patient are unnecessary.

Morris Kaplan.

Knüsel, O. **Contact lenses.** Ophthalmologica 116:225, Oct.-Nov., 1948.

The author's instrument for taking the exact measurements of the anterior segment consists of multiple levers on a central tube that contains the fixation point. By placing the tips of these levers against the sclera a tracing of the shape of the anterior segment is obtained which should permit the fitting of contact lenses without taking a mold.

Peter C. Kronfeld.

McKellen, G. D. **Conical contact lenses.** Brit. J. Ophth. 33:120-127, Feb., 1949.

The surface of a conical contact lens must rest on an area sufficiently behind the limbus to avoid pressure far enough from the edge of the lens to prevent the edge from digging into the eye, and it must rest on an area narrow enough to allow change to a new area as the eye moves. The fluorescein test is used to determine the correct angle of cone and the radius of the optic. The band of contact should be 2 or 3 millimeters behind the limbus and give corneal clearance when the eye is in the primary position. Most eyes can be satisfactorily fitted in considerably less time than is required

for other types. The veiling problem does not seem to be appreciably changed.

Orwyn H. Ellis.

Nordenson, J. W. **On the measure of the stereoscopic acuity of vision.** Brit. J. Ophth. 32:913-914, Dec., 1948.

In a discussion of the measure of stereoscopic vision for adoption of international standards the author reviews the previous reports and states that it seems appropriate to choose for this measure the stereoscopic radius of the examined person. This radius is the quotient of the pupillary distance and the stereoscopic angle of distinction.   Orwyn H. Ellis.

Pascal, J. I. **Role of corneal variability in contact lenses.** Ophthalmologica 116: 318-321, Dec., 1948.

Differences in corneal curvature account for the well-known phenomenon that eyes with widely different amounts of ametropia are corrected with the same contact lens.   Peter C. Kronfeld.

Pirenne, M. H. **Independent light detectors in the peripheral retina.** J. Physiol. 107:471, Sept. 30, 1948.

In 1945 the author observed that in the periphery the retina possibly was made up of a mosaic of units, each about two degrees in diameter, which, under near-threshold conditions of stimulation, behave as independent light-detectors. When a dim light is flashed over a wide field, only a few detectors among many might be stimulated. Despite this, such a field is not a discretely spotted pattern.

Using dim, constant light flashes (0.03 sec.) as a stimulus in a dark-adapted subject, a field of known area was uniformly illuminated and the light-detection reactions noted to test the above theory. Light detection reactions were noted as correct, incorrect, or absent after repeated light flash stimuli were tried in each case.   Francis M. Crage.

Posternak, J. **The visual field at high altitude.** Helv. Physiol. et Pharm. Acta 6:524-527, 1948.

The visual fields of six persons were measured for white, yellow, red, and blue at an altitude of 550 m. at Lausanne, and during a ten day stay at the Jungfraujoch, altitude 3450 m. The visual field for white showed no change during the stay at the high altitude. The visual fields for color were not conclusive.

R. Grunfeld.

Posternak, J. **Visual adaptation to darkness at Jungfraujoch.** Helv. Physiol. et Pharm. Acta. 6:516-523, 1948.

The authors measured the accommodation to darkness of six persons with a calibrated Engelkind and Harting adaptometer. Measurements were taken first in Lausanne at an altitude of 550 m., then during the course of a ten day stay at the Jungfraujoch, altitude of 3450 m., and then again in Lausanne. The stay at the higher altitude produced a lowering of the threshold which the author attributes not to an acceleration of adaptation but to an increased visual sensitivity.

R. Grunfeld.

Quinn, L. H. **Effect of insulin hypoglycemia on the ciliary muscle.** Arch. Ophth. 39:587-594, May, 1948.

Retinoscopic examinations were made before and during therapeutic insulin hypoglycemia. Paredrine hydrobromide ophthalmic, homatropine hydrobromide and atropine sulfate were used to dilate the pupils. Definite stimulation of the ciliary muscle was found in some eyes when paredrine was used as a mydriatic. This was most pronounced in the youngest patients and was greatest during deep insulin hypoglycemia. Homatropine partially abolished the stimulation of the ciliary muscle, and atropine did so almost completely. The fact that the refractive change which occurs during insulin hypoglycemia can be abolished by atropine cycloplegia indicates that it is due to stimulation of the parasympathetic nervous system. This observation is in agreement with other signs of stimulation of the parasympathetic system, namely, pinpoint pupil, slow heart rate, salivation and increased gastric secretion and motility.

Ralph W. Danielson.

Ríos Sasiain, Manuel. **The influence of monochromatic aberration on nocturnal myopia.** Arch. Soc. oftal. hispano-am. 8:925-938, Sept., 1948.

The object of this investigation was to determine the effect of spherical aberration on nocturnal myopia. In general, nocturnal myopia is accounted for to a small extent by Purkinje's shift from photopic to scotopic vision, and to a greater extent by changes in the crystalline lens. The effect of pupillary dilatation uncovers the marginal zones of the lens, and that brings about spherical aberration. Earlier investigations on the effect of the size of the pupil on the spherical aberration of the eye are reviewed, and the author's experimental armamentarium is described in detail. The charted and graphic data show that the eye is an overcorrected optic system in which the marginal zones of its refracting surfaces have a greater radius and a lesser curvature. The spherical aberration of the incident marginal rays is neutralized by the diminished curvature of the peripheral zones. Under physiologic conditions the eye has no spherical aberration; it therefore can not be a factor in the phenomenon of nocturnal myopia. Nocturnal myopia is greater with small than with large pupils.

Ray K. Daily.

Romero, Eduardo. **Neutral astigmatism.** Arch. Soc. oftal. hispano-am. 8:918-924, Sept., 1948.

Romero contends that all simple cylinders in the trial case should be replaced by crossed cylinders, because each simple cylinder exerts a spherical effect of one-half the strength of the cylinder. In crossed cylinders the spherical component is neutralized, and the effect on the refraction is only in one meridian, which he designates as neutral astigmatism.

Ray K. Daily.

Rubiño, A., and Pereyra, L. **The eye and the diencephalon.** Riv. oto-neuro-oftal. 23:69-84, March-April, 1948.

Extensive studies lead the writers to conclude that the daily life sense variations are a part of the metabolic and neuro-vegetative manifestation of the mesodiencephalic day-night rythm. (5 figures, 38 references.)

Melchiore Lombardo.

Sloan, L. L., and Wollach, L. **Comparison of tests for red-green color deficiency.** J. Aviation Med. 19:447-455, Dec., 1948.

The pseudo-isochromatic plates, anomaloscopic, the Rabkin test are evaluated. (2 figures, 7 tables). Irwin E. Gaynon.

Speiser, S. **The influence of the size of the pupil upon the critical flicker frequency.** Ophthalmologica 116:357-370, Dec., 1948.

The phenomenon of flicker is reviewed with special reference to its use as a clinical method of studying retinal function. Dilation of the pupil raises the critical flicker frequency while constriction of the pupil lowers it. These effects are due to variations in the amount of incident light and not to any action of the drugs upon the retina.

Peter C. Kronfeld.

Wagenaar, J. W. **So-called color stereoscopy.** Ophthalmologica 117:74-81, Feb., 1949.

Several phenomena of so-called color stereoscopy, that is, pseudo-plastic effects of flat color-containing patterns, are reviewed. Verhoeff described the optical illusion that the portions of a red line on a black and white background seem to be respectively nearer or farther away and he attributed the phenomenon to the effects of chromatic aberration and eccentricity of the lens system. Loewenstein and Donald observed the following phenomenon and believe that some psychologic factors at present unknown play a great part in producing it. When certain colored patterns are viewed against colored backgrounds for some time, the backgrounds change from surface colors to colored spaces in which the pattern seems to float. The phenomenon was found to be independent of color and almost as striking monocularly as binocularly. Wagenaar explains these and similar phenomena as partly optical, resultant from the superimposition of image and after image in oscillating fixation, and partly psychologic in terms of concepts of "Gestalt" psychology. Peter C. Kronfeld.

5
DIAGNOSIS AND THERAPY

Alcalá López, Antonio. **A dark room lamp.** Arch. Soc. oftal. hispano-am. 8: 946-948, Sept., 1948.

Alcalá describes an inexpensive arrangement consisting of 100 candle-power light globe in a dark housing with a small opening on each side. One serves as a source of illumination for ophthalmoscopy and has attached to it a holder for filters. A blue filter introduced into the holder provides a blue light for the examination of fluorescein-stained corneal defects. The other opening is connected to a tin tube capped with a holder for a condensing lens to focus the light on the cornea for removal of foreign bodies. The lamp is attached to the wall by an adjustable bracket. (1 figure.) Ray K. Daily.

Alcalá López, Antonio. **A model for a box of optotypes.** Arch. Soc. oftal. hispano-am. 8:901-906, Sept., 1948.

Alcalá López designed a new optotype box, with the special objective of discovering simulators, malingerers who hope to escape military service, as well as those who attempt to conceal their visual impairment. The instrument consists of an illuminated box, with a rotating chart on which one letter at a time is exposed. The chart contains letters, Landolt's rings, green and red letters for use with red and green spectacles and targets for estimation of heterophoria. The optotypes are printed on both sides of the paper and can be used directly at 5 meters or reflected in a mirror at 2½ meters. (4 figures.)

Ray K. Daily.

Arentsen, Juan. **Injection of air into the anterior chamber.** Arch. chilenos de oft. 4:485-490, 1947.

The author recommends careful consideration of this detail of technique, as described by Barraquer (Arch. Soc. oftal. hispano-am. April, 1946, abst. Am. J. Ophth., 1947, p. 348) for protection against contact of the iris with the operative wound, and for release of the vitreous from the operative wound in cases complicated by loss of vitreous. The author also speaks very favorably of the measure as applied to filling of the anterior chamber after suture of penetrating corneal wounds.   W. H. Crisp.

Bangerter, A. **Surgical experiences.** Ophthalmologica 116:214-216, Oct.-Nov., 1948.

To dilate the pupil before the intracapsular cataract extraction the author routinely uses homatropine. If this proves insufficient, he injects a small amount of cocaine and epinephrine subconjunctivally. He uses one Liégard suture and makes two basal iridectomies, one on each side of the suture. He administers eserine immediately after the delivery of the lens. The patient sits up in bed during the first 24 hours after the operation. Old age or acute dacryocystitis do not contraindicate a dacryocystorhinostomy. Bangerter advocates von Blaskovics' resection and advancement of the levator for most forms of ptosis. The sutures are tied over a metal strip which acts as a splint. Binocular dressing after tenotomy and advancement of the horizontal extrinsic muscles is unnecessary.

Peter C. Kronfeld.

Boles, W. McD. **Combined sodium "pentothal" and local anesthesia for selected cases of eye surgery, with a note on the additional use of curare.** South. M.J. 42:13-18, Jan., 1949.

The use of sodium pentothal is recommended because it does not explode, its use is simple and does not interfere with the operative field. Nausea and vomiting seldom occur postoperatively. There is also a lowering of intraocular tension which is favorable in cases of glaucoma.

Oxygen is advised for the cyanosis which may result from respiratory depression. The use of atropine intravenously prevents the sneezing and coughing that result from the stimulating effect of the sodium pentothal on the parasympathetic nervous system.

Local anesthesia is used to block pain stimuli and curare is added for further muscular relaxation. (1 figure.)

Herman C. Weinberg

Cripps, Mary. **The treatment of traumatic and inflammatory lesions by X rays and ultra-short wave diathermy combined.** Tr. Ophth. Soc. U. Kingdom 66: 333-345, 1946.

Ultra-short wave diathermy was extremely useful in the relief of pain due to mechanical factors such as the increased tension of glaucoma. Irradiation by X rays

alone was invaluable for the relief of nerve pain and prevention of irritation and sympathetic ophthalmia. The combined use of X rays and ultra-short wave in 195 patients caused improvement in various types of inflammatory and traumatic lesions. In 88 cases of acute trauma there was no occurrence of sympathetic ophthalmia. One patient in whom sympathetic ophthalmia had been diagnosed came for treatment 14 days after a penetrating wound with an increase of mononuclear leucocytes, and the attack was aborted. Ultra-short wave diathermy was usually used first to reduce the ocular tension, X rays relieved the pain and deep ciliary injection. A summary of the data is given. Beulah Cushman.

Davis, F. A. What the general practitioner should know about ophthalmoscopic examinations. Post grad. Med. 4:473-500, Dec., 1948.

The author advises a thorough understanding of the structure of the tissues which make up the fundus, some knowledge of the underlying disease processes which manifest themselves in these parts, and painstaking daily use of the ophthalmoscope. He describes the anatomy of the structures of the eye and pathologic changes found in diseases, with many illustrations of different parts of the eye. With accompanied illustrations, he discusses various diseases.

Theodore M. Shapira.

Endt, P. M., and ten Doesschate, J. A theoretical plan of a method for removing non-ferro-magnetic metallic intra-ocular foreign bodies by means of electro-magnetic forces. Brit. J. Ophth. 33:97-100, Feb., 1949.

The author presents the theory on which a method for removing non-ferro-magnetic metallic intraocular foreign bodies by building up high frequency-electro-magnetic fields is based. Copper,

for example, is pushed out of a magnetic field; with its generator behind the head a fragment of copper could theoretically be removed from the eye. A considerable amount of heat is generated in the particle. It is questionable whether a field of sufficient intensity can be produced and the difficulties of heat generation overcome. Orwyn H. Ellis.

Freusberg, O., and Weigelin, E. Some sources of error in measuring the diastolic pressure in retinal arteries after Bailliart. Klin. Monatsbl. f. Augenh. 113:209-220, 1948.

The speed with which the dynamometer is pressed down on the eyeball influences the diastolic pressure only little. The rapid production of pressure tends to give slightly higher values. The very first small pulsations are indicative of the diastolic pressure and to observe them a clear and sharply focused image of the optic disc is imperative. If they escape observation the readings will be too high. Repeated dynamometry tends to lower the intraocular pressure. The proper application of the instrument to the eyeball is important and the authors recommend that one assistant hold the instrument, a second read the scale, while the observer devotes himself fully to the observation of the fundus. Nervousness tends to raise the diastolic retinal pressure by about 4 mm. Hg in health and disease. A second reading after a 15-minute period of rest is suggested. The following routine is recommended: mydriatic, determination of brachial blood pressure, corneal anesthesia, ocular tension, dynamometry, repeated in 15 minutes, brachial pressure, and tension. Max Hirschfelder.

Giudice, Mario del. Retrobulbar saline injections in ocular therapy. Rev. brasil. de oftal. 7:69-73, Dec., 1948.

Beginning with ulcerative keratitis, the author tried the effect first of subcon-

junctival and then of retrobulbar injections of physiologic salt solution, which he later modified to one-percent solution of sodium chloride. He added one-percent novocain solution because of the pain produced. He gives briefly the details of several cases of inflammatory lesion in which such injections were beneficial. Pain and other inflammatory symptoms were diminished. W. H. Crisp.

Halbron, P., Lepage, F., Leconte, C., and Mawas, H. **Penicillin ophthalmic prophylaxis of the new-born.** Ann. d'ocul. 181:676-680, Nov., 1948.

In a series of 2000 births, no cases of gonorrheal conjunctivitis lasting more than 48 hours were observed after penicillin treatment. Two drops of a solution containing 5000 units per cc. were instilled immediately after birth and an ointment with 1000 units per gram was employed later. There were no corneal complications. In 22 infants conjunctivitis due to staphylococcus, streptococcus, pneumococcus, diplobacillus or Kochs-Weeks bacillus was promptly cured by this treatment. Chas. A. Bahn.

Halldén, U. **An instrument for the examination of the central field with binocular fixation.** Klin. Monatsbl. f. Augenh. 113:266-267, 1948.

The patient observes a spot of polarized light through polaroid lenses. A screen covered with aluminum paint reflects the spot of polarized light which can only be seen by one eye. The screen itself is diffusely illuminated by unpolarized light and its central fixation point can be observed binocularly. (1 figure.)
Max Hirschfelder.

Huber, A. **The effect of calcium therapy upon the eye.** Ophthalmologica 116:235-244, Oct.-Nov., 1948.

The effect of systemic calcium therapy upon the permeability of the blood-aque-

ous barrier was determined by observing the entrance into the aqueous of intravenously injected fluorescein. The rate of entrance of fluorescein into a normal eye is not altered by calcium therapy. In anterior uveitis, congestive glaucomas and ocular injuries the fluorescein method reveals a definite permeability-lowering, "anti-exudative" effect of systemic calcium therapy. Peter C. Kronfeld.

Jacobs, M. L. **Radiation therapy of eye diseases.** Ann. West. Med. and Surg. 3:68-69, Feb., 1949.

Inflammatory and non-neoplastic lesions are usually treated with beta radiation and neoplastic lesions with X or Gamma rays. The beta applicator emits rays which do not penetrate more than 2 mm. and are similar to the low voltage or Grenz rays. These have a healing effect on corneal ulcers and are also used for tuberculosis of the anterior segment, corneal scarring, granulation tissue and pterygium. Neoplastic diseases usually respond to X-ray or radium therapy.
Orwyn H. Ellis

Jacot, P. **The treatment of ocular tuberculosis with P501.** Ophthalmologica 116:290-292, Oct.-Nov., 1948.

P501, identical with promin, is perhaps the first step in the search for a satisfactory chemotherapeutic drug with specification on the tubercle bacillus. It may prove an adjuvant to streptomycin in ocular tuberculosis.
Peter C. Kronfeld.

Larsson, Harry. **An apparatus for the determination of the axial length of the eyeball.** Acta Radiol. 30:237-242, 1948.

The technique and instrument used by the author for the determination of the axial length of the eyeball, essential to the localization of intraorbital foreign bodies, is a modification of the Rushton procedure reported in 1938. The impor-

tance of knowing the exact axial length of the eyeball is apparent when it is realized that this measurement is not the same in all eyes.

Francis M. Crage.

Lauber, H. **The permanent magnet.** Klin. Monastbl. f. Augenh. 110:577-587, 1945.

Adequate electric current for electromagnets was often not available during the war. Permanent hand magnets of an iron-nickel-aluminum mixture proved very successful.

Gertrude S. Hausmann.

Lopez, Enriques M. **Improvement of the "Oculus" ophthalmoscope.** Arch. Soc. oftal. hispano-am. 8:1145-1148, Nov., 1948.

The author describes several modifications for improving the electric ophthalmoscope in use in Spain. They consist of an illuminating handle, which utilizes a nitra lamp of 8 volts and 3.8 amperes, a condensor, and a Rekoss disk provided with diaphragms of two sizes, two slits, and red and red-free filters. (1 figure.)

Ray K. Daily.

Loewenstein, A., and Foster, J. **Fatty embolism of the retinal artery found in eyes after enucleation and orbital exenteration.** Brit. J. Ophth. 32:819-823, Nov., 1948.

Four eyes removed by enucleation and by exenteration were examined internally with the slit lamp after equatorial section of the globe. In each case the central retinal artery was white for some distance from the disc. Serial sections revealed fatty embolism which was more or less fluid and consisted of a fine fatty emulsion which stained a shining red with scarlet red. No red blood cells were found within the milky areas, but distal to the embolism there was the regular column of blood. The presence of the fat is ex-plained by accidental cutting by the scissors of orbital fat with subsequent sucking of the fat into the artery and its emulsification by the orbital blood. This observation shows the ease with which fatty droplets can enter opened vessels and also a potential danger in foreign body extraction by the posterior route.

Morris Kaplan.

Moron-Salas, Jose. **On gonioscopy.** Arch. Soc. oftal. hispano-am. 8:1108-1113, Nov., 1948.

After a detailed discussion of the optical obstacles to be overcome before seeing the anterior chamber angle, Moron-Salas points out that his contact lens with a deep liquid chamber succeeds in eliminating the astigmatism of oblique rays, which is not achieved by the Goldman or Allen lenses. He admits that Troncoso's valid criticism that a reflected image of the angle loses something of its precision, applies to his lens. However, this is a defect of minor importance, far outweighed by the advantage of being able to do a gonioscopy through the corneal microscope. Ray K. Daily.

Neuenschwander, M. **Placenta therapy of retinitis pigmentosa.** Ophthalmologica 116:262-272, Oct.-Nov., 1948.

In about one-half of 27 patients with far-advanced retinitis pigmentosa who were subjected to tissue therapy after Filatof, results were positive, and at times amazing. In the discussion Bietti sums up his own experiences by saying that therapy with biogenic stimulants must not be considered a complete failure.

Peter C. Kronfeld.

Post, L. T. **Diagnostic significance of failing vision.** J.A.M.A. 139:303-305, Jan. 29, 1949.

This is a brief survey of some of the commoner causes of visual failure, with the note that mutual effort between the

ophthalmologist and practioners of other branches of medicine is very often necessary and of great benefit. The causes of visual failure are listed under the headings cornea, iris, ciliary body and choroid, retina, optic nerve, lens, vitreous, and disuse. Bennett W. Muir.

Richardson, A. W., Duane, T. D., and Hines, H. M. **Experimental lenticular opacities produced by microwave irradiations.** Arch. Phys. Med. 29:765-768, Dec., 1948.

The authors state that a direct single exposure of rabbit eyes to 12.24 cm.-microwaves at 5 cm. distance for 15 minutes with 100 watts power output resulted in the development of lenticular opacities after 3 to 9 days. After a single exposure the average temperature of the vitreous at the posterior pole of the lens was 55.1°C. and that of the cornea 49.4°C. A series of repeated exposures of a smaller magnitude resulted in lenticular opacities after 2 to 42 days. Four rabbits irradiated for 17 to 20 minutes at 5 cm. distance revealed cataract formations immediately. The practical applications of these microwaves are discussed.
Theodore M. Shapira.

Rintelen, F. **The treatment of blepharospasm with parpanit.** Ophthalmologica 116:217-220, Oct.-Nov., 1948.

Parpanit has proved beneficial in postencephalitic and arteriosclerotic forms of Parkinson's disease. The author advocates the use of the new drug in cases of idiopathic blepharospasm of older people in whom there is a possibility of an organic, extrapyramidal spastic mechanism.
Peter C. Kronfeld.

Trotter, R. R. and Grant, W. M. **Electronic flash (gas discharge) tube in photography of the anterior segment of the eye.** Arch. Ophth. 40:493-496, Nov., 1948.

For photography of the anterior seg-ment of the eye, an electronic flash tube of 9,500 lumen seconds' output provides more satisfactory illumination than the illuminants in common use for this purpose. Life-size color pictures can be taken with a desirably small lens aperture, yet with relatively little discomfort to the subject. Ralph W. Danielson.

6

OCULAR MOTILITY

Bischler, V. **Binocular triplopia.** Ann. d'ocul. 181:724-732, Nov., 1948.

This phenomena is not infrequently observed after operations for nonparalytic strabismus. Diplopia, in this condition, is avoided by suppressing the image of one eye, or by associating an eccentric image of one eye with a centric image of the fixing eye. After a review of several cases reported by Javal, Claasen, Bielschowsky, Tschermak, and Cass, the author explains the basic principles involved. Binocular triplopia may be observed from several months to years after strabismus operations. Chas. A. Bahn.

Boldrey, E., and Miller, E. R. **Unilateral paralysis of eye muscles associated with intracranial saccular aneurysms.** California Med. 70:96-98, Feb., 1949.

Congenital saccular aneurysms arise from weak areas in the walls of intracranial arteries where there has been incomplete involution of the embryonal vessels, or from defects at the point of bifurcation of larger intracranial vessels. They arise most frequently from the carotid artery or its principal branches. Three cases are reported in which the diagnosis was made early and treatment by intracranial ligation was successful. Unilateral ocular muscle palsy is an early diagnostic sign. Orwyn H. Ellis.

Lees, V. T. **A new method of applying the screen test for inter-ocular**

muscle balance. Brit. J. Ophth. 33:54-59, Jan., 1949.

The new test employs two Hess screen pointers, perpendicular to each other and similar, which are, however, not red and green and no colored goggles are necessary. Instead, a small plane mirror with a reflecting surface on each side bisects the right angle between the screens. The mirror blocks out the eye not being tested, yet the reflected image of the screen on that side is superimposed on the image of the other screen so that binocular fixation is obtained with monocular vision for the test object. Details of construction of the instrument are described.

Morris Kaplan.

Scheyhing, H. **Tenotomy in convergent squint.** Klin. Monatsbl. f. Augenh. 110: 313-321, May-June, 1944.

Of 134 patients who had been operated on for convergent strabimus in the years 1933 to 1942, 39 had developed divergence. In more than half of them the muscle was completely paralyzed, in the others considerably weakened. In 45 patients without secondary divergence the function of the internal rectus was impaired. The recorded data on all the patients are most thoroughly analyzed and it is obvious that tenotomy with or without a safety suture is an unreliable operation that frequently gives very poor cosmetic results. It should be abandoned in favor of the physiologically more appropriate strengthening of the lateral rectus by shortening and advancement. It is evident from the paper that the fundamental rule to measure the excursions of the eyes before and after the operation was completely neglected.   George Brown.

Tóth, Zoltan. **A new suture in resection of the muscle.** Klin. Monatsbl. f. Augenh., 110:321-324, May-June, 1944.

The muscle is exposed and isolated, cut at its insertion, pulled forward and two double-armed U-shaped sutures are inserted. One suture enters the distal edge of the conjunctiva, is passed through the muscle as far back as possible, eventually through the insertion and the conjunctiva. The second runs in the opposite direction, through the conjunctiva close to the cornea and muscle insertion, then again through the muscle as far back as possible, and the overlying conjunctiva. One of the sutures should be white, the other black. Finally the muscle is resected and the upper and lower black sutures simultaneously tied to the upper and lower white sutures respectively.

George Brown.

Urrets Zavalia, A. **Abduction in elevation.** Arch. de oft. de Buenos Aires 23: 124-134, April-June, 1948.

Because of the action of the inferior oblique muscles the visual axes tend to diverge when the gaze is directed upward, and conversely they tend to converge when directed downward. This must be recognized in the interpretation of examinations of muscle function. (6 figures, 12 references.)   A. G. Wilde.

7

CONJUNCTIVA, CORNEA, SCLERA

Appelmans, M. **The keratoconjunctivitis sicca of Gougerot-Sjögren.** Arch. d'opht. 8:577-589, 1948.

Appelmans discusses in detail the historical, clinical, and pathologic features of this syndrome and its relation to the syndrome of Mikulicz. He points out that Gougerot, a prominent French dermatologist, first described the essential features of the syndrome in 1926, before Sjögren's description of it appeared in 1933. Appelmans considers that Mikulicz's disease is a separate entity in spite of the fact that the two syndromes have much in common. He stresses the role of lacrimal dys-

function in the production of filamentous keratitis, which may be a facultative and episodic complication of keratoconjunctivitis sicca. He points out, however, that filamentous keratitis may follow other unrelated conditions such as relapsing keratitis, dendritic keratitis, chronic glaucoma, or herpes zoster.

In discussing the etiology the author considers in turn the avitaminosis theory, the sympathetic dysfunction theory, the neurotoxin theory, and the endocrine dysfunction theory. He suggests the possibility of a chemical mediator, which he calls secretin, which might be concerned in initiating the function of the serous glands. He considers that vasomotor action supplements the chemical action and concludes that the sexual hormones may be concerned with the vasomotor action. He notes that the majority of medications are poorly tolerated in keratoconjunctivitis sicca. Hormonotherapy has been successful early in the disease and closure of the canaliculi has been valuable.

P. Thygeson.

Boulanger, Jacques. **Vitamin D-2 and old tuberculin in tuberculous keratitis.** L'Union med. du Canada 77:1439-1441, Dec., 1948.

An alcoholic solution of vitamin D-2 containing 300,000 international units per cc. is recommended as a valuable adjunct to old tuberculin in the treatment of tuberculous interstitial keratitis. Three cases are reported. The dosage recommended is 100 drops three time a week for the first week, 100 drops twice a week for the next three weeks, and 100 drops per week for the following six months. Daily milk and additional calcium are indicated.

Irwin E. Gaynon.

Cometta, F. **The preservation of corneas in liquid paraffin.** Ophthalmologica 116:307-310, Oct.-Nov., 1948.

In four of ten keratoplasties done with donor corneas that were preserved and stored in paraffin oil after the method of Buerki, the grafts remained clear. In one case the donor cornea had remained in paraffin for 42 hours.

Peter C. Kronfeld.

Friede, R. **Keratoplasty for total leucoma. (A case of total sclerosis of the cornea.)** Klin. Monatsbl. f. Augenh. 113: 147-152, 1948.

Penetrating keratoplasty has been disappointing in eyes with total and adherent leucoma. Central transplants become opaque and, when too large, develop into a staphyloma. Total replacement of the cornea also is not promising. Friede used a modification of the usual method in eight eyes of which 83 percent healed with opacification, 17 percent were partially opaque, and none remained entirely clear. He tried this procedure in a patient who had a severe sclerosing keratitis with highly inflamed and vascularized corneas. Vision was reduced to recognition of hand movements. A crescentic mass of corneal tissue of one eye was removed down to Descemet's membrane. The defect was filled with a similar shaped donor implant which was held in place by sutures. Six months later a small penetrating keratoplasty was performed in the center of the cornea on the inner curvature of the implanted crescent. This implant stayed clear for several weeks, but got slightly hazy later. In the other eye a large part of the cornea was removed down to Descemet's membrane. The central parts of Descemet's membrane were then removed, leaving a peripheral margin as support for the relatively large donor transplant. The implant became moderately hazy in the following months. The author feels that a large partially penetrating keratoplasty with preservation of Descemet's membrane preparatory to a subsequent smaller total keratoplasty may improve the

outlook for these unfavorable cases of total leucoma.   Max Hirschfelder.

Frischer, M., Jablonski, W., and Loebel, M., The treatment of allergic external diseases in Palestine. Ophthalmologica 116:335-349, Dec., 1948.

Gutmann thinks that vernal conjunctivitis in Palestine is due to an allergy to fungi superimposed on a chronic infection. Specific desensitization and removal of the focus of infection are effective treatment which, however, is too complicated and costly to be used on a large scale. Privine and antistine topically, plus antistine systemically, have given favorable results.   Peter C. Kronfeld.

Gorman, J. E. The Stevens-Johnson syndrome; report of two cases. U. S. Nav. M. Bull. 49:50-54, Jan., 1949.

The author reviews the literature and reports two cases.   Orwyn H. Ellis.

Gray, J. D. A. Meningococcal conjunctivitis. Brit. M. J. pp. 17-18, Jan. 1, 1949.

Purulent conjunctivitis in a 3½-year-old boy healed within eight days under local therapy with 30-percent sodium sulphacetamide, penicillin solution (2,000 units per ml.), and atropine. Meningococcal conjunctivitis is more frequent than is commonly thought; it is erroneously diagnosed as gonococcal. (References.)
          Bennett W. Muir.

Healy, J. J. Two cases of exogenous tuberculous conjunctivitis displaying Parinaud's conjunctivo-adenitis syndrome. Tr. Ophth. Soc. U. Kingdom, 66: 455-466, 1946.

Two patients had granulomatous swelling of the upper tarsal conjunctiva which seemed to be a primary exogenous infection by tubercle bacilli, and swelling of the parotid gland on the same side as in typical Parinaud's conjunctivitis. Tuber-

cle bacilli, in one of the human type and in the other bovine, were found in the tissue and in the discharge. Both patients recovered with minimum scarring on general hygienic and local care. No tuberculin was used.   Beulah Cushman.

Howell, S. C. and Benton, Curtis, Jr. Keratitis nummularis (Dimmler); report of five cases. South. Med. J. 42:94-97, Feb., 1949.

In four of five cases both eyes were involved. The disease is usually unilateral. Slitlamp examination showed lesions immediately behind Bowman's membrane, which had dense circular centers and sharply defined edges, surrounded by a less dense halo. These lesions were facets with shallow edges. None of the patients had positive tests for brucellosis. (3 figures).   Bennett W. Muir.

Klainguti, R. Chestnut bur injuries of the eye. Ophthalmologica 116:247, Oct.-Nov., 1948.

Eye injuries due to chestnut burs are apparently quite common in Switzerland. During harvesting a chestnut may strike the eye and one or several burs may become implanted in the cornea. The protruding portion of the bur usually breaks off, but removal is accomplished quite easily in most cases. Penetration of the tip of a bur into the anterior chamber is rare.   Peter C. Kronfeld

Marín Amat, Manuel. Two cases of fatty degeneration of the cornea, consecutive to corneal herpes. Arch. Soc. Oftal. hispano-am. 8:891-896, Sept., 1948.

One case followed an insignificant corneal injury. Fifteen days after the removal of a corneal foreign body the cornea presented a typical picture of herpetic keratitis, and in spite of therapeutic procedures total fatty degeneration of the cornea, with loss of vision ensued. In the second case there was no

trauma, and three weeks after the onset of corneal herpes the cornea had undergone a complete fatty degeneration. The pathogenesis of fatty corneal degeneration is discussed in detail. The invisible lipoids of the cornea become transformed into visible lipoids through lack of oxidation. The condensation of the fine invisible fatty emulsion in the cellular protoplasm is followed by reaction similar to that of a foreign body in the cells of the reticuloendothelial system; at first the reaction is defensive, but then it proceeds to proliferation of fibroblasts and cicatrization. Inadequate local oxidation is the basic pathologic process, but excessive cholesterol in the diet, disturbances in the lipoid metabolism, hereditary predisposition, and vascular disturbances may be important factors. It is suggested that procedures stimulating local oxidation, such as subconjunctival injections of oxygen should be tried in the therapy of these refractory diseases.

Ray K. Daily.

Mitter, S. N. Scleral degenerations: a case of scleromalacia perforans. Brit. J. Ophth. 32:899-904, Dec., 1948.

The author reviews the literature on scleral degenerations briefly and points out their differences. He reports a cystic swelling of the sclera of a young man which extended into the cornea and progressed until the eye became atrophic.

Orwyn H. Ellis.

Motolese, F. Pseudotrachomatous acute follicular conjunctivitis, due to nonhemolytic streptococcus. Boll. d'ocul. 27:456-463, July, 1948.

Discussing three cases, Motolese revives the famous autoinnoculation experiment performed by Theodor Axenfeld decades ago in order to show the difficult differential diagnosis between conjunctival diseases with follicular formation other than trachoma. Therapeutically he

favors gentle massage of the everted lids with a cotton applicator soaked in mercury bichloride solution. K. W. Ascher.

Orzalesi, F. One more case of probably herpetic involvement of the corneal endothelium. Boll. d'ocul. 27:424-438, July, 1948.

Orzalesi describes an acute unilateral eye disease in an otherwise normal patient, 50 years of age. It started as an iritis with severe neuralgia of the first branch of the fifth nerve, and later affected the central area of the posterior corneal strata, where intense haziness and pseudoprecipitates were observed. Folding of Descemet's membrane and marked edema of the corneal stroma and epithelium followed. The author classified the disease as Favaloro's keratoendothelio-Descemetitis and assumed that herpes was the cause. He wonders whether the herpes virus can become localized in the endothelium and on Descemet's membrane as it does in the corneal epithelium and Bowman's membrane and whether a deep herpetic keratitis can originate from a primary invasion by way of the aqueous humor. (3 figures.) K. W. Ascher.

Orzalesi, F. An unusual type of fatty degeneration of the cornea in a trachomatous eye. Boll. d'ocul. 27:561-584, Sept., 1948.

A 70-year-old man had trachoma with entropion and trichiasis in his only eye and severe scarring of the cornea which was gray with partially protruding yellowish dots. Tension was normal. A corneal transplantation was preformed and the excised disc was examined histologically. The excised disc showed irregularity and increase in layers of the epithelium, the basal cells of which were elongated and rested upon the corneal fibers where the membrane of Bowman had been destroyed; up to 15 rows of

polygonal cells could be counted in some places. There, however, places where the epithelium was very thin and only one layer of keratinized cells covered the parenchyma. The latter showed severe destruction; many spongy cells like those in-xanthomatosis were seen between the ruptured, barely recognizable fibers. Only Descemet's membrane had persisted; its endothelial lining was deficient in many regions. Fat staining revealed the presence of numerous fatty deposits of granular or droplet shape. The pathogenesis of these changes is discussed. (Stereophotograph, 5 photomicrographs, 45 references.) K. W. Ascher.

Radnót, M. Posterior progressive scleritis. Ophthalmologica 116:167-171, Sept., 1948.

Radnót reports a case of chronic rheumatoid arthritis and chronic bilateral uveitis of more than ten years' duration. Because of intractable pain, glaucoma, poor light projection and exophthalmos one eye was removed. The histologic examination revealed a noncharacteristic diffuse uveitis and a chronic proliferative scleritis of the posterior half of the sclera which had been greatly thickened and transformed into granulation tissue.
Peter C. Kronfeld.

Sie-Boen-Lian. Epidemic keratoconjunctivitis in Batavia during 1946 and 1947. Ophthalmologica 116:86-100, Aug., 1948.

An epidemic of epidemic keratoconjunctivitis broke out in Batavia in May, 1946, reached a first peak in November, 1946, and a second one in July, 1947. During the Japanese occupation the author did not see a single case of the disease. He believes it was brought in by the Indian and English army. Indonesians, Chinese and Caucasians appeared to be equally susceptible. The clinical course did not differ significantly from the European or American form of the disease. The author found systemic sulfathiazole therapy beneficial in that the conjunctival condition usually improved rapidly within five days from the inception of the sulfonamide treatment. The literature is reviewed. Peter C. Kronfeld.

Sorsby, A., and Ungar, J. Preliminary note on the treatment of hypopyon ulcer by crystalline penicillin in adrenalin in doses in excess of 50,000 units injected by subconjunctival or retrobulbar routes. Brit. J. Ophth. 32:878-881, Dec., 1948.

The authors found that amounts of penicillin injected subconjunctivally up to 500,000 units at 24 hour intervals were well tolerated, and most hypopyon ulcers responded rapidly and satisfactorily. This is a preliminary report with most promising results thus far. Retrobulbar injections of similar doses appear to be somewhat less efficient, but show clinical response. Orwyn H. Ellis.

Wolff, J. E. Ocular complications in erythema exudativum multiforme with mucous membrane lesions. Brit. J. Ophth. 33:110-119, Feb., 1949.

The author reviews the literature of erythema exudativum multiforme, also known as Stevens-Johnson disease and presents two case reports. The etiology is unknown but four causes have been suggested: hematogenous tuberculosis, virus, vitamin deficiency and allergy.
Orwyn H. Ellis.

Zibikowski Margarida, E. Some details of pterygium surgery. Arch. Soc. oftal. hispano-am. 8:1017-1023, Oct., 1948.

All pterygium operations can be divided into two groups: those in which the raw surface of the sclera is covered completely, and those in which several millimeters of sclera adjacent to the limbus are left exposed. The operation practiced by the author belongs to the latter

group. The cornea is cleared meticulously of every vestige of the pterygium with a knife made of a portion of a razor blade; a flap is then cut away from the lower portion of the pterygium and the remainder is buried under the conjunctiva of the lower fornix. Healthy conjunctiva is thus pulled down from above to cover the space occupied by the pterygium, and an elliptical area of sclera adjacent to the cornea is left exposed. (4 figures.)

UVEA, SYMPATHETIC DISEASE, AQUEOUS

Caballero del Castillo. **Iridodiastasis.** Arch. Soc. oftal. hispano-am. 8:897-900, Sept., 1948.

A case of this rare congenital anomaly in a woman, 20 years old, is reported. In the inferior external portion of the iris a hole occupied the outer half and was bridged by some thin iris tissue strands. The pupil was slightly oval, and displaced up and in. This anomaly is the result of imperfect closure of the embryonal cleft. The differential diagnosis between a congenital and an acquired traumatic lesion is discussed in detail, and it is pointed out that Dupuy-Dutemps' statement that in congenital anomalies the pupil is round is not always true. A large congenital deformity may give rise to some distortion of the pupil. (1 figure.)

Dufour, R. **Ocular manifestations of early pulmonary tuberculosis.** Ophthalmologica 116:298-303, Oct.-Nov., 1948.

In young adults shortly after their first pulmonary infection with tuberculosis, that is during the stage of the primary complex, serous iridocyclitis and retinal periphlebitis took a torpid course, probably because of a low degree of local (ocular) allergy to tuberculin.

Peter C. Kronfeld.

Fleming, Norman. **A case of pigmented leiomyoma of the iris.** Brit. J. Ophth. 32:885-892, Dec., 1948.

The author presents an interesting report of a case of pigmented leiomyoma of the iris, which was completely removed by iridectomy. Section showed spindle cells, palisading of nuclei, and a regular pattern of cell bundles. Myoglial fibers were demonstrated, pigment was present throughout the tumor, and the diagnosis of melanotic neuroectodermal leiomyoma was justified. A review of the other three published cases is given. These tumors are believed to arise from the neural epithelium just as does the dilator muscle. All four published cases have occurred in the lower half of the eye.

Orwyn H. Ellis.

Gómez da Silva, Avelino. **A case of cilium in the anterior chamber.** Arq. brasil. de oftal. 11:153-159, 1948.

In a man of 35 years, examined because of hypertensive retinitis, a cilium lay across the anterior chamber, adhering by its bulbous root to the posterior surface of the iris. There were slight corresponding spots of clouding of the lens capsule and cornea. Removal was not undertaken. (References.)

Greeves, R. A. **A contribution to the microscopic anatomy of the sympathizing eye.** Brit. J. Ophth. 32:545-550, Sept., 1948.

The history and histologic description of sections of 13 cases of the sympathizing eye in sympathetic ophthalmia are presented briefly. The diagnosis was quite obvious from the history. All patients had had surgery on the other eye. The time of onset after the surgery varied from 5 weeks to 9 years. In seven cases the inflammatory cells were purely lymphocytes and plasma cells, in six cases epithelioid cells wer present and in three of these, giant cells were seen. The

only constant factor common to all was the presence of an iridocyclitis which varied considerably in character and intensity. In five eyes the choroid was normal and in 6 there were areas of infiltration with lymphocytes and plasma cells only. The author concludes that no special characteristic of the sympathetic inflammatory process is invariably found in the sympathizing eye.

— Morris Kaplan.

Halberg, J. P., and Doret, J. P. Tuberculosis of the choroid in a case of miliary tuberculosis treated by streptomycine. Ann. d'ocul. 181:485-492, Aug., 1948.

A 16-year-old boy with acute familial pulmonary tuberculosis developed cervical adenopathies with the other classical signs of miliary tuberculosis. During five months he received approximately 250 grams of streptomycine beginning with a dosage of three grams daily which was gradually decreased with the clinical arrest of the disease. During the attack a central choroidal focal lesion was observed in the right eye, and several nodules in the periphery of the fundus of the other. These regressed without anterior uveal involvement and without appreciable loss of sight. The treatment is believed to have favorably influenced healing. — Chas. A. Bahn.

Iñigo, L. Ophthalmia produced by caterpillar hair. Arch. Soc. oftal. hispano-am. 8:988-1001, Oct., 1948.

Iñigo reports a case of ophthalmia nodosa, in a man, 21 years old, who was struck in the left eye with a caterpillar. A violent inflammatory reaction was set up, and five days later his eye presented a picture of an acute keratoconjunctivitis, with numerous corneal infiltrations. A number of vascularized nodules were also found in the bulbar conjunctiva. With the slitlamp, the lower half of the cornea was found studded with a multitude of fine needles, some of which were in irregular clumps or bundles. They were lying in the parenchyma either parallel to the epithelium or obliquely, reaching to Descemet's membrane and deeper. An attempt at removal soon demonstrated the futility of the task, because of the deep situation of some of these needles. Under symptomatic treatment the case ran its usual clinical course. It begins with a phase of violent inflammatory signs and symptoms which lasts from five to eight days; this is followed by a second period, in which the inflammatory symptoms subside, vision is recovered, and the cornea acquires a tolerance to the encapsulated foreign bodies; this period lasts about three months. There is, however, always a danger of recurrence of the inflammatory phenomena, with loss of the eye from glaucoma, cyclitis, or retinitis. A detailed description is given of the caterpillar hair and it is demonstrated that the fine needles penetrating the cornea or skin are the contents of a pouch on the dorsal protuberances of the caterpillar, which forms a part of a complicated defense mechanism. The tiny needles are barbed in their posterior portion, which makes their removal difficult after they become imbedded in the tissue. They are propelled deeper into the tissue by ocular movements, by blinking, and by rubbing the eyes. The acute inflammatory phenomena are caused by poison carried by these invading needles. Because of late complications the prognosis should be guarded. Treatment should consist of removal of the invaders, whenever possible; when they are too numerous, mydriatics and lubricating ointments should be used to hasten encapsulation of the foreign bodies at their point of entry. Klainguti, R. Circumscribed iris atrophy in Behcet's disease. Ophthalmologica 116:211, Oct.-Nov., 1948.

In a typical case of Behcet's disease (recurrent iritis with hypopyon, associated with recurrent oral aphthae and genital ulcerations) small areas of circumscribed stroma atrophy of the iris developed and increased in size and number as the disease continued to recur.

Peter C. Kronfeld.

McPherson, S. D., Jr. **Sympathetic ophthalmia: a review of 61 cases.** South. M. J. 42:120-124, Feb., 1949.

This is a review of 61 cases of sympathetic ophthalmia observed in the Wilmer Institute in the 10 years that preceded 1948. The shortest interval between injury and onset of the disease was seven days and the longest 23 years; in all but five the disease began after three weeks to one year. Many types of therapy were used but the value of any particular type of treatment is very difficult to assess. In 10 percent the final vision was 20/20 in the sympathizing eye, in 33 percent 20/100 or better, in 46 percent 10/200 or less, and in 5 cases total blindness resulted. It seems wise to reserve enucleation for patients in whom sympathetic ophthalmia has been known to exist in the second eye for one week or less. (5 tables, references.) Bennett W. Muir.

Oxilia, Efisio. **Ocular pathology in Grassi's hereditary elastodystrophy (Cannata's systemic type of dyselastic mesodermosis).** Ann. di ottal e clin. ocul. 73: 385-427, July, 1947.

Three cases of angioid streaks, two of which were associated with pseudoxanthoma elasticum, are presented and discussed at great length, with particular reference to pathogenesis. The evidence points to a generalized dysembryoplastic mesenchymopathy, that is, a congenital anomaly of development affecting particularly the elastic tissue but also all the connective tissue of the body in general. A choroidal angiopathy may explain the association of angioid streaks with macular degeneration of the Junius-Kuhnt variety and with peripheral pigmentary disturbances in the retina. Only 13 cases of angioid streaks have been previously reported in Italy, whereas their frequent occurrence has been noted in Anglo-Saxon countries. (2 figures, bibliography 1936-1946.) Harry K. Messenger.

Redi, F. **Senile changes in the choroid, studied histologically.** Boll. d'ocul. 27: 531-547, Aug., 1948.

The eyes from 41 cadavers were studied histologically for senescence of the choroidal tissue. The results are meticulously evaluated and shown in five photomicrographs and in two tables. Thickness and blood vessel content of the choroid decrease with increasing age; the connective tissue of the choroid becomes sclerotic with advancing age and diminishes in extent. Elastic fibers become more numerous throughout life. The decrease in thickness of the choroid is least marked in the vicinity of the ciliary body; the average thickness in the equatorial region and in the posterior polar region is greatest in the 25 to 50-year age group. It was 132 and 170 µ respectively, whereas in persons younger than 25 years these figures were 119 and 134 µ, and after the age of 50 years, 97 and 114 µ. (References.) K. W. Ascher.

Samuels, B. **Participation of the ocular appendages in sympathetic ophthalmia and its bearing on enucleation.** Brit. J. Ophth. 32:569-575, Sept., 1948.

Samuels is convinced that, although sympathetic ophthalmia is primarily a disease of the inner eye, the appendages of the eye may also be involved simultaneously, and after enucleation of the exciting eye these infected appendages are often left in the orbit to spread the disease. He agrees with Parsons that the immediate etiology of sympa-

thetic ophthalmia is a filtrable virus and that this virus enters the eye at the time of the penetrating injury. The virus leaves the inner eye by the same routes as those chosen by the cells of a malignant melanoma of the choroid. It passes through the sclera by way of the numerous emissary veins into Tenon's space. The infection spreads to become a leptomeningitis of the intervaginal space and actually may appear as a collar around the optic nerve. It is certain, however, that the infection is not transferred to the other eye through the optic nerve and chiasm because the opposite nerve never shows signs of descending inflammation. In removing the exciting eye as a preventive measure before any signs of infection have appeared, the ordinary technique may be employed with safety. If, however, the signs of sympathetic ophthalmia are present, enucleation should include resection of the optic nerve and of the inferior oblique muscle as far back as possible and the wound should be left open to drain. If some degree of vision remains in the exciting eye enucleation should be postponed. The benefits of the operation are problematic and sacrificing even the faintest vision is not justified. (5 figures.)   Morris Kaplan.

Snell, A. C. Postoperative iridocyclitis. New York State J. Med. 48:2710-2714, Dec., 15, 1948.

Inflammation is produced by the irritants which are liberated from the injured cells. Bacterial toxins and allergic conditions influence the reaction of the tissues. Traumatic iridocyclitis is discussed. Postoperative iridocyclitis is reviewed from the standpoint of the tissue damage caused by the cutting, tearing and crushing which occurs during surgery. Exposed lens cortex is a source of toxic degenerating tissue, and makes possible irritating bacterial products and allergic reactions. Intraocular hemorrhage can cause iritis after surgery by the liberation of toxic degenerative products and also by the ability of the blood to organize a fibrous tissue. The methods in which a loss of vitreous can cause iridocyclitis are reviewed. (8 figures.)

H. C. Weinberg.

Verhoeff, F. H. Histological findings in a case of angioid streaks. Brit. J. Ophth. 32:531-544, Sept., 1948.

The histologic sections of the eye of a 50-year-old patient who died of cardiovascular failure and who had previously been observed to have angioid streaks were studied. Only two deviations from the normal were found. Bruch's membrane was definitely basophilic and there were breaks in it with gaping edges. The change in the staining of the membrane is ascribed to calcification but this calcification must differ from that which is common in senile eyes because in the latter the elasticity of the choroid is absent and there is no gaping of the edges in rupture of the membrane. The ophthalmoscopic appearance of the streak is a result of the visibility of the chorio-capillaris through the break. Three disturbances associated with angioid streaks too often to be merely coincidental are cardiovascular disease, Paget's disease and pseudoxanthoma elasticum. No satisfactory explanation for this association has been suggested.   Morris Kaplan.

Verrey, F. Environmental effects upon intraocular inflammations. Ophthalmologica 116:204-210, Oct.-Nov., 1948.

A general discussion of some of the factors that influence the course of uveitis by altering the susceptibility of the affected person is presented.

Peter C. Kronfeld.

Weekers, L., and Weekers, R. Technique of iridencleisis. Brit. J. Ophth. 32: 904-910, Dec., 1948.

The authors describe a modified iridencleisis. They make a small Graefe incision under a conjunctival flap. The prolapsed iris is torn radially and both pillars are left under the flap. The wound is closed with interrupted sutures. The gonioscopic findings are clearly illustrated.

Orwyn H. Ellis.

Witmer, R. **Cavernous hemangioma of the choroid.** Ophthalmologica 116:285-288, Oct.-Nov., 1948.

A bluish-gray, choroidal tumor in a 33-year-old man caused gradual atrophy and later detachment of the overlying retina. Since the tumor slowly increased in size and opaqueness (upon translumination) the eye was enucleated and found to harbor a typical cavernous hemangioma of the choroid. Peter C. Kronfeld.

GLAUCOMA AND OCULAR TENSION

Arruda, J. D. **Iridencleisis.** Arq. brasil. de oftal. 11:145-151, 1948.

For the Portuguese reader, a brief summary of the history, the classical steps, and some authors' modifications of the operation is given. (References.)

W. H. Crisp.

Barkan, O. **Goniotomy for the relief of congenital glaucoma.** Brit. J. Ophth. 32:701-728, Sept., 1948.

In the past this disease has resulted in a high percentage of blindness. Barkan urges earlier and more accurate diagnosis of congenital glaucoma and prompt treatment by goniotomy. He has operated on 76 eyes with satisfactory result in 66. The symptoms of increased intraocular pressure in congenital glaucoma may be present at birth, or their onset may be sudden during the first few months of infancy and consist of cloudy cornea, photophobia and signs of irrita-

tion and congestion. Rarely there is a gradual onset without signs of congestion. Pressure should be measured with a tonometer under ether anesthesia which must be sufficient to assure complete relaxation.

The initial cloudiness of the cornea is associated with roughening of the corneal epithelium and is the chief cause of the irritative symptoms and photophobia. If allowed to persist, it is superseded by permanent scarring with associated irregular astigmatism and amblyopia. Glaucomatous atrophy of the optic nerve is the exception and occurs late. If increased tension is made normal by goniotomy soon after its inception transparency of the cornea is almost completely restored and maintained and vision develops normally. The technique, mode of action, advantages, disadvantages, indications and contraindications of goniotomy are described in detail. (12 figures.)

Morris Kaplan.

Blodi, F. **Nevus flammeus of the face and glaucoma.** Ophthalmologica 117:82-89, Feb., 1949.

The clinical findings in two cases of nevus flammeus of the face with unilateral glaucoma but without enlargement of the globe are reported. The second patient had epilepsy and his ailment may, therefore, be a case of Sturge-Weber syndrome. Peter C. Kronfeld.

Brückner, R. **The effect of drugs upon the ocular hypertension produced by Trendelenburg's position.** Ophthalmologica 116:200-203, Oct.-Nov., 1948.

A short stay in Trendelenburg's position raises the ocular tension in man and rabbits. The effect upon this ocular tension of various drugs was studied under conditions of topical as well as systemic administration. The author concludes that enhancement of the aqueous drain-

age by way of Schlemm's canal is only *one* of the factors through which drugs can lower the ocular tension.

Peter C. Kronfeld.

Busacca, A. **Gonioscopic examination of a case of hydropthalmia.** Ann. d'ocul. 181:627-628, Oct., 1948.

In a 13-year-old girl with corneas measuring 14 mm., the peripheral areas of the iris were atrophied and the insertion of the iris was displaced by the trabeculum. These changes resulted in a circular goniosynechia, and Schlemm's canal contained blood. The author believes that a vascular communication must have existed between this canal and the conjunctival veins, or the former would have been bloodless from pressure of the contact glass. Chas. A. Bahn.

Dellaporta, A. **Late infection after filtering operations.** Ophthalmologica 116:322-334, Dec., 1948.

Eleven cases of late infection after filtering operations are reported. Nine occurred after trephinings, two after sclerectomies after Lagrange. The value of sulfonamides is uncertain since milk injections alone control the infection. Antibiotics were apparently not available. Two eyes became phthisic.

Peter C. Kronfeld.

Desvignes, P., and Naudin. **Nonperforating cyclodiathermy in the treatment of certain glaucomas.** Arch. d'opht. 8:589-592, 1948.

The authors have employed nonperforating cyclodiathermy according to the technique of Weekers in the treatment of glaucoma when intraocular surgery was contraindicated. They have used it successfully in cases of secondary glaucoma, in infantile glaucoma, and in chronic simple glaucoma after failure of fistulizing operations. They mention satisfying results in two cases of traumatic subluxation of the lens with secondary glaucoma. In hemorrhagic glaucoma the results obtained were variable and in absolute glaucoma poor.

The technique consisted of retrobulbar anesthesia followed by applications of the flat electrodes of Coppez to the sclera 5 to 7 mm. from the limbus on the meridians of 12, 3, 6, and 9, eight applications in all. The apparatus is regulated so that a temperature of 90°C. is maintained for 10 seconds. No complications have been observed. The drop in tension is not immediate but gradually develops after a slight and transient rise in pressure. The full effect is not attained until the tenth to fifteenth day. If there is a recurrence of elevated tension, the operation can be repeated. This procedure does not replace the ordinary fistulizing operations but is a valuable supplement to them.

P. Thygeson.

François, J. **Cysts of the ciliary processes observed gonioscopically.** Ophthalmologica 116:313-317, Dec., 1948.

For the relief of acute congestive glaucoma an iridencleisis was performed on the only seeing eye of a male patient, 32 years of age. The postoperative course was uncomplicated and a filtering scar developed. The ocular tension has remained below 25 mm. Hg Schiøtz for four years. Gonioscopic examination of the area of the operation reveals the inner aperture of the operative wound to be tightly healed. In the pseudocoloboma created by the meridional iridotomy a number of ciliary processes are plainly visible. Two small cysts are situated between the processes. The contents, as well as the major portion of the wall of the cysts, are colorless.

In the author's experience the inner aperture of the iridencleisis wound is always completely closed, without the

slightest dehiscence between the wound lips. The incarcerated iris functions as a drain. The existence of a filtering scar is not necessary for a tension-lowering effect of the iridencleisis. The latter is chiefly due to a modification of the fluid exchange and of the metabolism in the iris and in the ciliary body.

<div align="right">Peter C. Kronfeld.</div>

Goldmann, H. **Outflow pressure and glass-rod phenomenon.** Ophthalmologica 116:195-198, Oct.-Nov., 1948.

Pressure exerted on the eyeball by means of an instrument like the Souter tonometer placed against the center of the cornea, increases the intraocular pressure and modifies the circulatory conditions in the aqueous veins. The smallest amount of pressure thus exerted which causes a noticeable widening of an aqueous vein is called outflow pressure. This pressure is related to the resistance which the aqueous encounters during its passage from the anterior chamber to the anterior ciliary veins, and to the amount of aqueous passing through these channels. The fact that in wide-angle glaucoma Ascher's glass-rod phenomenon is nearly always negative indicates that in this disease the pressure in the canal of Schlemm is relatively low. The outflow pressure, however, is definitely increased. Goldmann concludes that the resistance between anterior chamber and canal of Schlemm is abnormally great in chronic simple (wide-angle) glaucoma.

Grant, W. M. **Miotic and antiglaucomatous activity of tetraethyl pyrophosphate in human eyes.** Arch. Ophth. 39:579-586, May, 1948.

Tetraethyl pyrophosphate is comparable to physostigmine and di-isopropyl fluorophosphate in miotic activity and may be used when there is local sensitivity to other miotics. In several instances,

0.05 to 0.1-percent solution of the drug in peanut oil used twice a day was more effective than 4 percent pilocarpine nitrate used more often. An excessive dose may cause aching about the eye, and in certain eyes an increase in tension occurred. The drug acts as an inhibitor of cholinesterases. Ralph W. Danielson.

Kapuscinski, W. J. **Contribution to the clinical study of glaucoma.** Ann. d'ocul. 181:542-555, Sept., 1948.

In approximately 40 patients the usual provocative tests for glaucoma were of little practical value. Diminished light adaptation is of greater value diagnostically. Several case histories of juvenile glaucoma are presented to illustrate that miotics such as pilocarpine may increase ocular tension and that atropine may lower tension. The characteristic disk excavation as well as central and peripheral visual changes of glaucoma are not infrequently associated with normal tension as is illustrated by several case reports. No single theory yet presented explains all the objective symptoms of the juvenile type, nor the acute and chronic primary types of glaucomas in adults.

<div align="right">Chas. A. Bahn.</div>

Di Luca, G. **Biomicroscopic examination of the cicatrices of antiglaucomatous operations.** Rassegna ital. d'ottal. 17:304-317, Sept.-Oct., 1948.

Di Luca bases an explanation of the mechanism of action in successful surgery in glaucoma on the postoperative biomicroscopic examination of 23 eyes and a study of the literature. Anastomosed collateral circulation develops across the area of operation for the normalization of tension. These subconjunctival vessels unite with the uveal vessels to supplement the outflow of fluid from the globe. (7 figures.)

<div align="right">Eugene M. Blake.</div>

Majoros, J. **Postmortem ocular pressure.** Arch. Ophth. 39:665-668, May, 1948.

The ocular pressure falls at the moment of death, but some pressure remains. In numerous ophthalmic and general diseases the pressure is sometimes as low as it is in death. The glaucomatous eye retains its pressure after death and after enucleation. .Ralph W. Danielson.

Monfette, Claude. **Treatment of chronic glaucoma with nicotinic acid.** L'Union med. du Canada 77:1433-1435, Dec., 1948.

The author states that glaucoma is a diencephalic affection, a dysfunction of the thalamus and hypothalamus with vasomotor predominance involving the capillary circulation in which there is localized edema and an increase of blood and interstitial fluids in the eyeball.

Nicotinic acid is used in a concentration that will not impair the choroidal circulation. A test dose of 2 mgm. is given intravenously. The vision and tension are taken every 15 minutes for one hour. If the reaction is favorable, the recommended dose is I mgm. in distilled water twice a day by mouth. It is not indicated in acute glaucoma, secondary glaucoma with anterior segment lesions, hemorrhagic glaucoma, old chronic glaucoma, and when the tension is above 50.
Irwin E. Gaynon.

Much, V. **Contributions to the surgical treatment of glaucoma.** Ophthalmologica 117:36-42, Jan., 1949.

The author reports in considerable detail a case of bilateral chronic noncongestive glaucoma for the relief of which a sclerectomy after Lagrange was performed on the right eye and a cyclodialysis on the left eye. Although neither operation accomplished normalization of the tension the operations may be considered as successful. The tensions of the cyclodialyzed eye were, in general, higher than those of the other; and a better visual field was preserved. The lowering of tension is not the only beneficial result of surgery. Peter C. Kronfeld.

Posner, A., and Schlossman, A. **Treatment of glaucoma associated with iridocyclitis.** J.A.M.A. 139:82-86, Jan. 8, 1949.

The use of mild miotics in combination with phenylephrine hydrochloride ("neosynephrine hydrochloride") is advocated for the syndrome of glaucomatocyclitic crises and for other conditions in which posterior synechiae are not formed. It seems more effective than for secondary glaucoma. Theodore M. Shapira.

Posner, A., and Schlossman, A. **Development of changes in visual fields with glaucoma.** Arch. Ophth. 39:623-639, May, 1948.

Approximately 2,000 visual fields in 350 cases of primary glaucoma were studied and classified. The development of the characteristic field changes was analyzed by breaking down these defects into their component units, namely, the arcuate scotoma, the nasal field defect and the juxtacecal step. A relationship exists between the circulatory and the neural elements of the glaucomatous field and most defects result from a mixture of these two components. The authors feel that damage to nerve fibers at the margins of the cup and by traction from the receding lamina cribrosa is not of greatest importance. Ralph W. Danielson.

Radnót, M. and Németh, B. **The eye first affected in glaucoma.** Ophthalmologica 117:60-62, Jan., 1949.

The records of 902 patients with glaucoma show that either eye may be affected first, whereas Holst found the left eye involved more often.
Peter C. Kronfeld.

Schmelzer, Hans. **Investigations of glaucoma in the present war.** Klin. Monatsbl. f. Augenh. 110:289-296, May-June, 1944.

Before the war the author had found a hypercholesteremia, a positive xanthoprotein reaction, frequently an increased bilirubin index in the blood-serum and a disturbance of the liver function in the majority of his patients with glaucoma. During the war the blood cholesterol was decreased because of restriction in fat, alcohol and coffee. Thus the war imposed a "liver-saving diet" on patients with glaucoma. Twenty-one patients with glaucoma who had had an average blood cholesterol of 273 mg. percent before the war were re-examined. The average blood cholesterol was 202 mg. percent and there was no progress of the glaucoma, except in three patients. In two of the latter, well nourished farmers, the tension was high, visual fields and central vision had become worse and the blood findings were the same as before the war.

George Brown.

Silva, M. A. da. **Iridencleisis.** Arq. brasil de oftal., 11:122-132, 1948.

The technique of the Holth operation is described for the reader of Portuguese with a tabular statement of the results obtained in series of cases of trephining, cyclodialysis, and iridencleisis respectively. Iridencleisis is as yet very little used in Brazil. (6 figures.)

W. H. Crisp.

Stocker, F. W. **New ways of influencing intraocular pressure.** New York State J. Med. 49:58-63, Jan. 1, 1949.

The principles upon which glaucoma is treated by miosis or surgery are reviewed. Of 32 negroes who had been treated by cyclodiathermy puncture twenty had normal pressures almost three years later, seven were improved and five were not improved. The place of Etamon and Pris-

col and their paralyzing effects on the autonomic nervous system in causing lowered ocular tension is discussed. The use of the rice diet met with some success in reducing ocular tension under certain circumstances. Rutin was used to prevent the increase in permeability of the blood-aqueous barrier which occurs after the use of miotics. The increased outflow of aqueous produced by miosis is often nullified by this increased permeability of the blood-aqueous barrier. Twenty-six patients were given 20 mg. of rutin three times a day; there was improvement in 17, no improvement in 5 and questionable improvement in 4. The author recommends dosage up to 50 mg. of rutin three times a day. (4 figures, 3 tables.)

H. C. Weinberg.

Vidal, F., Brodsky M., and Travi, O. C. **Dynamic ocular tone and metabolic disturbances.** Arch. de oft. de Buenos Aires 23:92-93, April-June, 1948.

The elevation of tension is but a stage in the evolution of glaucoma, and is primarily dependent on changes in the metabolism of the various ocular tissues. The abnormal alterations are made manifest by asthenopia, headaches, diminution in the sensitivity to light, and visual clouding and result from increased cholestrinase in the retina, emotional upsets, infections, and abrupt alterations of temperature.

A. G. Wilde.

Villaseca, Alfredo. **Nonperforating cyclodiathermy in the treatment of glaucoma.** Arch. chilenos de oft. 4:425-456, 1947.

The author begins this 32-page paper by urging emphatically that recent studies have deposed the idea that the fundamental change in glaucoma occurs at the angle of the anterior chamber. He uses an electric needle whose head is perfectly flat and 1.75 mm. in diameter. After dis-

section of conjunctival and subconjunctival tissue, the exposed sclera must be rendered perfectly dry and free from blood. Each application is made for five seconds only, using firm pressure (Albaugh and Dunphey recommend 8 to 10 seconds). The intensity of current considered adequate is such as to cause first retraction and then a "parchment-like" effect in the sclera for 0.5 to 1 mm. around the electrode. The applications are made over a quadrant or more and as far back as 5 to 6 mm. from the limbus when the previous tension was below 35 to 40 mm., and up to one half of the circumference if the tension was above 40 to 50 mm. There should be a frank rise of ocular tension at the end of the operation. If there is no appreciable rise of tension at that time, some of the applications should be intensified or additional applications made. The eyeball is painful for 24 hours, more or less.

In 17 of the author's 30 cases the tension was reduced to normal by diathermy. Further deterioration of vision or visual field was not produced. However, there was a definite corneal anesthesia in the sector operated upon. Usually this did not have major consequences, but in two patients serious trophic changes occurred. Once or twice the tendency of the eye to atrophy was accelerated. The author regards this as the operation of choice in hemorrhagic glaucoma, in painful ab-absolute glaucoma, and in rubeosis of the iris; and it was also serviceable in the chronically glaucomatous aphakic eye, in advanced simple chronic glaucoma with greatly restricted visual field, in posterior luxation of the lens, in glaucoma of aniridia, and in buphthalmos. (Tabular summary; references.)   W. H. Crisp.

Weekers, L. and Weekers, R. Nonperforating thermometric cyclodiathermy in treatment of hypertensive uveitis. Arch. Ophth. 40:509-517, Nov., 1948.

The diathermy apparatus, thermometer circuit and technique of operation are described; 12 to 16 coagulations 8 mm. from the limbus are made through the conjunctiva. The operation is similar to that of Albaugh and Dunphy, but differs in that the Weekers do not regard dissection of the conjunctiva as necessary, they do not limit themselves to one-half the circumference of the ciliary body because previous experimental researches have demonstrated that when the operation is performed in a small territory it becomes necessary to use a more intense diathermy current to obtain a sufficient effect on the ocular pressure, and use a thermometer electrode, which enables them to regulate their intervention and to repeat it under identical conditions. The authors used to practice iridencleisis ab externo in the treatment of ocular hypertension with uveitis, but now prefer nonperforating cyclodiathermy. The main indications for thermometric nonperforating cyclodiathermy are uveitis complicated by intraocular hypertension, hypertension persisting after a filtering operation, painful absolute glaucoma, and intraocular hypertension after corneal transplantation.   Ralph W. Danielson.

Weekers, L., Weekers, R., and Roussel, F. The mode of action of the nonperforating cyclodiathermy. Ophthalmologica 117:65-73, Feb., 1949.

A flat round electrode, 0.75 mm. in diameter, at 90°C. is applied to the sclera 7 mm. from the limbus for 15 seconds in 20 areas. On patients with chronic primary or iridocyclitic glaucoma operated by this method the author studied the pupillary responses to the topical application of drugs. Since the cyclodiathermy injures the ciliary nerves, parasympathetic and sympathetic denervation is expected. The irides of these patients proved highly sensitive to mecholyl and epinephrine and insensitive to cocaine.

The response to eserine was equivocal. The authors conclude that their operation causes extensive denervation of the anterior uvea. The resulting permanent loss of the vasoconstrictor control causes alterations in the fluid exchange of the eye.   Peter C. Kronfeld.

CRYSTALLINE LENS

Andradee, Lopes de. **The intracapsular cataract extraction.** Ophth. Soc. U. Kingdom 66:241-245, 1946.

The author has tried to simplify the operative procedure by opening the eyelids with stitches and fixing the eyeball by means of sutures passed through the superior, inferior and internal rectus muscles.   Beulah Cushman.

Comberg, W. **Surgery of unilateral cataract.** Klin. Monatsbl. f. Augenh. 110: 340-343, May-June, 1944.

The peripheral vision of an aphakic eye without correcting lens is about one-third normal 25 degrees eccentrically, and about two-thirds at 55 degrees. The extraction of a unilateral cataract seems indicated because of the considerable gain in visual field even though optical correction is not tolerated. The total disability is not more than 10 to 15 percent.
                      George Brown.

Crámer, F. E. K., and Foglia, V. G. **Experimental diabetic cataracts in rats.** Arch. de oft. de Buenos Aires 23:101-117, April-June, 1948.

Extirpation of 95 percent of the pancreas will regularly produce cataract in the rat in a minimum of seventy days. The major changes are in the cortex.
                      A. G. Wilde.

Csillag, F. **Loop extraction of subluxated cataracts.** Ophthalmologica 116:172-176, Sept., 1948.

Attempts to grasp the lens capsule with a smooth capsule forceps may fail because of defectiveness of the zonule, hypertension within the lens and its capsule, and fluidity of the lens cortex. When the zonule is defective the author recommends extraction with a modified loop which is introduced into the anterior chamber in front of the lens and applied like a lasso to the portion of the equator opposite the incision. When the defect is in the lower part but the upper is intact the incision is made above, as usual, and after a total iridectomy the loop is carefully slipped into the anterior chamber and around the lower part of the equator of the lens. Once this has been accomplished the extraction of the lens is easy.
When there is hypertension in the lens, or the cortex is fluid the author recommends needle puncture of the lens near the equator above.
                      Peter C. Kronfeld.

Fanta, H. **Rupture of the wound following cataract operation.** Ophthalmological 116:149-161, Sept., 1948.

This report from Lindner's clinic in Vienna stresses the value of corneoscleral sutures which "proved a sure protection against ruptures of the cataract incision, even during the bombing of the city." In the routine technique of intracapsular cataract extraction at Lindner's clinic a small limbus-based flap is prepared and one de Mendoza (McLean) suture is placed in the corneosclera at 12 o'clock. After an incision with the Graefe knife a sliding forceps extraction is performed by means of an Arruga forceps applied just anteriorly to the upper equator. The suture is tied and two peripheral iridectomies are made, one on each side of the suture. Hilding's experimental work (American Journal of Ophthalmology 28:871, 1945) is quoted in detail and corroborated by clinical observations.   Peter C. Kronfeld.

Franceschetti, A. **Cataract operation on an eye with sympathetic ophthalmia.** Ann. d'ocul. 181:530-534, Sept., 1948.

A successful cataract extraction was performed on a woman, aged 25 years, who, 12 years previously, had sympathetic ophthalmia. The injured eye was removed nine weeks after an injury from a dart. The sympathizing eye which had long been inactive had good light projection. A keratome incision was followed by iridectomy, detachment of synechia, and lens extraction with a spoon. The ultimate corrected vision was 0.3. A brief survey of the literature follows.

Chas. A. Bahn.

Franceschetti, A. **Successful cataract extraction from an eye with sympathetic ophthalmia.** Ophthalmologica 116:213, Oct.-Nov., 1948.

The author reports the case of a young woman who at the age of three years sustained a perforating injury to her right eye. Nine weeks later the left eye developed sympathetic ophthalmia which took a prolonged and severe course, in spite of the enucleation of the injured eye (time of enucleation not stated). When the patient was 13 years old, two iridectomies were attempted but accomplished only partial removal of iris stroma. The posterior layers of the iris could not be lifted up with forceps. Several years later the uveitis appeared inactive, the cornea had undergone band-shaped degeneration, there was seclusion of the pupil and a complicated cataract. The patient was operated on again. The author succeeded in making an iridectomy. Through the coloboma he introduced a spatula and broke most of the posterior synechiae. The lens was delivered with a loop. Three years later the patient's corrected vision was 0.3 and the eye was quiet.

Peter C. Kronfeld.

Giri, D. V. **Technique of intracapsular extraction of cataract with retention of** conjunctival bridge. Tr. Ophth. Soc. U. Kingdom 66:247-260, 1946.

The author advised the use of nembutal and of liberal local anesthetics, and atropine and adrenalin for dilatation of the pupil, but no retrobulbar injection. A conjunctival bridge is made at the time of the corneal section, with or without an iridectomy. The lens can usually be removed in its capsule. (5 figures.)

Beulah Cushman.

Holland, H., and Holland, R. W. B. **Notes on 221 intracapsular cataract extractions performed in three weeks at Khairpur in 1947.** Brit J. Ophth. 33:101-106, Feb., 1949.

The author performed these intracapsular extractions by the Smith method which is recommended only for experienced surgeons. Only two cases of retinal detachment have been observed in over 30,000 intracapsular extractions at this center. If the upper pole of the lens does not present immediately after the beginning of the delivery, the lens is extracted extracapsularly. Orwyn H. Ellis.

Hruby, K. **Simplified corneoscleral suture in cataract extraction.** Wien. klin. Wchnschr. 60:748-749, Nov. 19, 1948.

Hruby describes his modification of the Mendoza suture as practiced by Lindner and claims for it the advantages of the firm wound closure that Lindner's technique gives and much less technical difficulty. After preparation of the conjunctival flap he makes two short superficial incisions, instead of one, in the outer sclera to receive the suture, one at the limbus, the other 1 to 2 mm. behind it. There is ample room for the cataract knife between them and it rarely cuts the suture, an accident which is relatively frequent with Lindner's operation. In 252 cataract operations this accident occurred only twice, whereas with Lindner's technique in 95 operations the su-

ture was cut 11 times. A detailed description of the operative procedure is given. (1 figure.)   B. T. Haessler.

Kirby, D. B. The rupture of the zonule in intra-capsular cataract extraction—a new method. Brit. J. Ophth. 33:3-21, Jan., 1949.

The rupture of the zonula fibers is essential in the intracapsular extraction of the lens and the finding of many resistant zonules is accounted for by the number of immature cataracts extracted. The point of rupture of the fiber is just at its junction with the capsule which accounts for the absence of retinal separation. A common error of judgement is to attempt to rupture all zonules by the same method instead of adapting a suitable method to each eye. For rupturing the fibers indirectly, Kirby prefers a combination of the three methods, pressure from without, traction on the capsule, and rotation of the lens in the capsule. After making the section, he uses enough pressure on a point within the corneal limbus at the 6, 8 and 4-o'clock positions to indent the cornea 2 to 3 mm. and to make the wound gape. Pressure outside the limbus is unnecessary, ineffectual and dangerous. Almost simultaneously with the point pressure and while the wound is gaping, the capsule forceps is applied to the anterior capsule just below the equator. He much prefers the forceps to the loop, the pointed hook, the electro-coagulation electrode and the various types of erisiphakes. Kirby describes his new forceps which is a combination of the Kalt, Arruga and Verhoeff forceps and has a cylindrical handle. His traction is actually a rotation from side to side and he often uses two forceps rather than one. Direct rupture of the zonule is indicated when the zonule is unduly resilient, when patient and surgeon are both relaxed, and when the zonule can be made tense by elevating the lens at least 3 mm. He has

used direct rupture for 10 years with excellent results. (7 figures.)

            Morris Kaplan.

Knapp, Arnold. (Bowman Lecture.) The present state of the intracapsular cataract operation. Tr. Ophth. Soc. U. Kingdom 66:133-178, 1946.

The history of intracapsular cataract surgery is reviewed from 1903 when Henry Smith developed the intracapsular technique in India to the present time.

Three features of the anatomy of the zonule are important in the understanding of the technique of the intracapsular extraction; they are the origin of the fibers, the independence of the zonular membrane from the hyaloid part of the vitreous, and the insertion of the zonular fibers in the lense capsule. The knowledge of the slight variation in the thickness of different parts of the lens capsule and of the consistency of the lens makes it possible to decide where the capsule should be grasped. The lens can usually be more easily dislodged tangentially, but the thickness, tenseness and elasticity of the lens capsule are important. The older the patient (usually over 60 years of age) the easier the subluxation, and intracapsular extraction is not suitable in persons under 45 years of age.

Smith brings about subluxation of the lens by pressure straight back on the lower half of the cornea, which causes the head to present, and pressure downward on the lowest peripheral point causes the lens to somersault. A slight turning of the lens around in the transverse axis aids in breaking the zonular fibers. The suction cup devised by Halen and popularised by Barraquer also turns the lens on the transverse axis. Verhoeff subluxates by torsion and traction. Kalt introduced the use of capsular forceps and now the use of different types of forceps with some counter pressure is almost universal. The capsule forceps

must be small and firm, the speculum light in weight and easily removable with one hand. Akinesia and retrobulbar injection which temporarily weakens the extraocular muscles, especially the inferior rectus, simplify the operation. The use of corneoscleral sutures ensures a quick restoration of the anterior chamber. There should be no traction of the flap and no constriction of the tissues. The injection of air into the anterior chamber counteracts any tendency to anterior adhesion of the hyaloid membrane or of the iris.

The complications of intracapsular operation depend on the proper selection of the cataract. The intumescent cataract with swollen cortex is tense and most difficult to hold with blunt forceps; in its removal the suction procedure is helpful. Many nuclear cataracts, posterior cortical cataracts and sclerosed lenses are the most favorable for the intracapsular procedure. The loss of vitreous is the most important complication and may occur directly after the incision, during subluxation or after delivery of the lens. The loss of vitreous or injury to it is often followed by a pupil which is drawn up because of cicatrical contraction of the vitreous and adhesions of the iris. Rupture of the capsule during extraction of the cataract may be serious if the hyaloid membrane is also ruptured. Iridocyclitis occurs after intracapsular extractions but is usually very mild. In the more severe types it may be followed by deep vascularization of the cornea and glaucoma. Glaucoma is usually secondary to anterior adhesions of the capsule to the incision or it may follow an anterior adhesion of the hyaloid membrane to the posterior surface of the cornea or to the incision. Trauma to the corneal endothelium may cause the hyaloid membrane or iris to become adherent before the anterior chamber is established. The injection of air or salt solution into the anterior chamber at the close of the operation will help

prevent an anterior adhesion of the vitreous body. Detachment of the retina usually seems to be associated with low grade cyclitis. Complications of the intracapsular operation are difficult to treat satisfactorily. The future of the operation lies in the reduction of the difficulties by improvement in the methods of operating.

Beulah Cushman.

Knüsel, O. **Two cases of electric cataract.** Ophthalmologica 116:212, Oct.-Nov., 1948.

In the two cases reported the electric shock consisted of very brief exposures to electric current (8,000 to 11,000 volts). The lens opacities which had remained almost stationary for several years, apparently were the only permanent residue of the electric shock. The latent period of electric cataract is stressed.

Loutfallah, M. **Bilateral detachment of the retina in aphakia.** Eye, Ear, Nose and Throat Monthly 28:73-75, Feb., 1949.

The author reports an interesting detailed case report of bilateral detachment of the retina successfully operated upon with scleral diathermy. The lenses had been removed six and nine years previously, extracapsularly and without discission. The literature is reviewed.

Orwyn H. Ellis.

Samuels, Bernard. **Proliferation of the epithelium of the lens.** Tr. Ophth. Soc. U. Kingdom 66:467-491, 1946.

The author summarizes the proliferation of the epithelial cells of the lens in 185 cases of nontraumatic cataract. The greatest proliferation was found in corneal scars, spontaneous iritis and detachment of the retina and when a low grade chronic alteration in the metabolism had existed over the longest period. The least proliferation occurred with in-

traocular tumors and glaucoma. (28 figures.)   Beulah Cushman.

Sobhy Bey, M. **My method of cataract extraction.** Ophthalmologica 116:38-42, July, 1948.

The professor emeritus at the hospital Kasr-el-Aini in Cairo (Egypt) describes the technique of cataract extraction at which he arrived after 40 years of extensive practical experience. Until 1926 his method of choice was the extracapsular extraction of mature cataracts. A trip to Barcelona in 1926 revolutionized his technique and he became an ardent follower of Barraquer. Sobhy Bey describes his procedure as follows. A patient with bilateral advanced cataract is operated upon when the vision of the better eye becomes too bad to follow his profession. The eye with the advanced cataract (which is usually mature) is operated on by the extracapsular method. A V-shaped incision is made in the anterior lens capsule by means of the cystotome and the piece of capsule thus outlined is removed with a toothed forceps. After expression of the nucleus the anterior chamber is thoroughly irrigated. As soon as this eye has become quiescent, the second eye is operated upon by the intracapsular method. If the patient has only one eye and the indications are against total extraction (as in high myopia), the extracapsular extraction method is used, and that after repeated discission in order to be certain of the complete ripeness of the lens.

       Peter C. Kronfeld.

Venco, Luigi. **A "two-stage" capsulolenticular cataract extraction.** Ann. di ottal. e clin. ocul. 73:428-438, July, 1947.

Venco describes and discusses his modification of the intracapsular method of extraction with forceps. The cataract is removed in two stages at a single oper-ation. First a large peripheral capsulotomy is done above along the margin of the widely dilated pupil, and the lens substance is removed by pressure and irrigation; then the capsule is grasped with a special forceps and extracted. In the majority of cases the entire capsule can be removed, but the operative result is satisfactory if only enough of the capsule is removed to leave clear the pupillary area. This operation is especially recommended when the unruptured capsule is hard to grasp. If the capsule ruptures when it is grasped in the course of the usual method of intracapsular extraction, the operation may be satisfactorily concluded by this two-stage method. (2 figures.)

RETINA AND VITREOUS

Alvares Pires, Ari. **Inferoversion of the retina.** Rev. brasil. de oftal. 7:75-86, Dec., 1948.

Two cases are reported. The first patient was a man of 32 years, who at the age of 16 years had developed cataract in the right eye as the result of an explosion, but had obtained a fair visual field after extracapsular extraction. Two weeks ago this eye had lost its vision without apparent cause. The detached retina lay almost entirely below the horizontal line, depending from a promontory which corresponded to the optic disc. No vessels could be seen. There was a line of tear in the upper inner quadrant. The sec-

ond patient had received a kick in the right eye during a football match, and the retinal condition was apparently somewhat similar to that of the first patient. W. H. Crisp.

Alvares Pires, Ari. **Cyst of the vitreous.** Arq. brasil de oftal. 11:133-134, 1948.

Routine ophthalmoscopic examination in a man of 23 years disclosed a black spot in the lower part of the pupillary area. With the slitlamp the spot was found to be pigmented, about 1 mm. in diameter, and attached to the lowest third of the posterior lens capsule. The vitreous adjacent to the lower pole of the cyst contained numerous scattered pigment points resembling those of the cyst. There were no remains of the hyaloid artery. The author accepts Uribe Troncoso's opinion that the pigment deposits in the vitreous originate in the uvea.

W. H. Crisp.

Arruga, H. **How can we improve the operative results of surgical detachment?** Arch. Soc. oftal hispano-am. 8:1085-1089, Nov., 1948.

The percentage of successful surgical results can be raised by attention to certain details. In vitreous hemorrhage, not part of recurrent retinal hemorrhages in the young, retinal detachment should be suspected, and the patient put to bed. Once a diagnosis is made a binocular bandage is of undoubted value in arresting the extension of the detachment. Direct and indirect ophthalmoscopy should be used to find the hole and study it in detail. Arruga implies that the value of indirect ophthalmoscopy is not appreciated in the United States, and that failure to make use of it accounts for some of our surgical failures. In early cases, with slight detachment at the level of the hole and good pupillary dilatation operation should be done promptly. An inflam-

matory reaction and pupillary rigidity are indicative of a mild uveitis, and operation should be postponed until these symptoms subside. In general, operation should be performed at the time when the detachment is minimal. Marked detachment at the level of the retinal hole is an indication for delay until the detachment flattens and the retina becomes reapplied. Eyes with large holes and disinsertions do not improve on rest in bed, and immediate surgery is indicated. When there is failure of the retina with a small hole to become reapplied after rest in bed the prognosis is poor, since it is evident that the choroid's capacity for absorbing the subretinal exudate is impaired. If after 18 or 20 days of bed rest the retina has not reapplied, further delay is useless, although surgical success is improbable. An extension of the detachment in spite of rest in bed is an indication for delaying operation lest the choroid may not absorb the subretinal exudate, or perhaps respond with an inflammatory reaction. Absolute postoperative rest in bed is essential, and its duration is determined by the structural changes in the coagulated area. The development of an adhesive retinochoroiditis is indicated by the appearance of pigment in the gray coagulated zone. When being transported patients should be seated so that the jars of the vehicle are not transmitted to their head.

Ray K. Daily.

Babel, J. **Senile macular pseudotumors.** Ann. d'ocul. 181:613-620, Oct., 1948.

In senile disciform and allied retinopathies the following stages occur. An edema begins at the posterior pole and involves the choriocapillaris and lamina vitrea. Irregularities in Bruch's membrane, hyaline band-like deposits in the choroidal capillaries, and local elevations in the pigment epithelium appear. The

hyalin may penetrate the subadjacent exudate with resulting vascular perforations. It may also provoke new exudates with resulting proliferation of fibroblasts and scar tissue. The consequent vascular sclerosis may also be associated with degenerative changes of the circinate type. The frequent hereditary tendency shows that constitution is an important factor. Several illustrative cases are presented.

Chas. A. Bahn.

Babel, J. The histologic development of the senile pseudotumor of the macula. Ophthalmologica 116:277-278, Oct.-Nov., 1948.

The primary changes are in the lamina vitrea and in the choriocapillary layer. The lamina undergoes irregular thickening and hyaline spurs extend into the choriocapillary layer. On the other side of the lamina an exudate forms which lifts the pigment epithelium off the lamina. The latter becomes permeable to cells and capillaries. The whole disease may be due to a selective sclerosis of the choroidal vessels. Peter C. Kronfeld.

Ballantyne, A. J. The state of the retina in diabetes mellitus. Tr. Ophth. Soc. U. Kingdom 66:503-543, 1946.

The progressive changes in diabetic retinopathy are described and the finding in 178 patients out of 561 diabetics are exhibited.

The duration of the diabetes is of the greatest consequence, whereas the treatment with insulin is not. The typical retinopathy may occur in patients in whom the blood sugar had been controlled without insulin. Of 170 patients with diabetic retinopathy 120 had diastolic pressure of less than 100 mm. Hg and only 50 above that level. Probably a chronic stasis on the venous side of the retinal circulation produces anoxia and nutritional changes in the walls of the capillaries and veins. About one-third of the diabetic patients develop pathologic changes in the retina.

Beulah Cushman.

Bedell, A. J. Ophthalmoscopy and operations for reduction of high blood pressure. Arch. Ophth. 40:483-492, Nov., 1948.

"At the beginning of any consideration of hyperpiesia it must be understood that the vast majority of patients with hypertension present no lesion of the fundus. This statement cannot be repeated too often." The ophthalmologist should be able to state with reasonable certainty whether a given fundus pattern indicates a favorable postoperative outcome, one of doubtful value, or a disappointing result. He must know the life history of the retinal variations and estimate the life expectancy of the individual patient. If the patient has no serious involvement of the heart, kidneys or cerebral vessels and no retinopathy, the ophthalmologist can sanction operation. If a retinopathy is present, with cotton wool patches, hemorrhages and exudates, approval may be given only when the results of physical and laboratory tests seem to warrant an operation, with the expectation that life will be lengthened. If the patient has definite arteriosclerosis, as indicated by white-walled vessels; if he has round, deep, red, granular retinal hemorrhages; if there is considerable retinal edema, as evidenced by a decrease in the visibility of the retina, or if there are intense, widespread edema of the retina and obscuration of the margins of the discs, with or without newly formed vessels on or about the disc; if there has been recent closure of a retinal artery or vein, operation is contraindicated. If there is marked papilledema with narrowing of the arteries or fulness of the veins, operations should be opposed.

Ralph W. Danielson.

Blum, J. D., and Babel, J. The histologic differences between true and pseudo-retinitis pigmentosa. Ophthalmologica 116:261, Oct.-Nov., 1948.

In the true degenerative forms of retinitis pigmentosa the primary site of the process is in the cells of the visual neuroepithelium. All other changes are secondary developments. Pseudo-retinitis pigmentosa comprises the chorioretinal diseases due to lues, scarlet fever, measles, vaccination or German measles of the mother. In the latter condition the primary retinal change is in the pigment epithelium. In the other postinflammatory retinal diseases the retinal vessels are primarily involved. Peter C. Kronfeld.

Blum, J. D., and Babel, J. Differential histologic diagnosis of retinal and pseudo-retinal pigmentary degeneration. Ann. d'ocul. 181:468-474, Aug., 1948.

In primary retinal pigmentary degenerations the neuro-epithelium is primarily involved; in the secondary group it may or may not be involved histologically. The successive stages are usually neuroepithelial degeneration, pigment proliferation with migration toward the inner retina, vascular changes with shrinkage, disorganization of the inner retinal layers, gliosis, and atrophy of the retina and disk. In secondary pigmentary involvements, the neuroepithelium is frequently only slightly involved. After fetal rubeola the clinical appearance of the retina may resemble primary pigmentary retinosis, but histologically, the condition is usually nonprogressive and the neuroepithelium is less damaged. A clinically similar picture is the salt and pepper fundus that is usually associated with congenital lues, in which the neuroepithelium is secondarily involved. (6 figures.) Chas. A. Bahn.

Boyden, R. C., and Kettering, H. A. Occlusion of the center retinal vein; report of a case treated with heparin. U.S. Nav. Med. Bull. 48:912-913, Nov.-Dec., 1948.

Heparin therapy was begun 24 days after the onset of thrombosis of a central retinal vein and was given for nine days. Clotting time was kept as close to twenty minutes as possible. Vision on admission to the hospital ten days after the onset was 20/300; 28 days later it was 20/200 in the periphery and 20/300 centrally. The authors suggest further studies using 100 mg. every four hours for the entire day and night. H. C. Weinberg.

Busacca, A. Retinal lesions caused by lightning. Ophthalmologica 116:141-143 Sept., 1948.

Busacca describes and depicts the ophthalmoscopic findings in a case of central retinopathy caused by lightning. The lesion consisted of edema of the macula with stellate opacities and a small detachment. The author wonders whether the lesion is to be ascribed to the electrical discharge or to the dazzling of the dark-adapted eye.

Peter C. Kronfeld.

NEWS ITEMS

DEATHS

Dr. Julian Baker Blue, Memphis, Tennessee, died January 25, 1949, aged 64 years.

Dr. Louis Bothman, Chicago, died January 19, 1949, aged 55 years.

Dr. Robert James Curdy, Kansas City, Missouri, died December 15, 1948, aged 80 years.

Dr. Jule T. Elz, Saint Louis, Missouri, died April 22, 1949, aged 53 years.

ANNOUNCEMENTS

ORTHOPTIC INSTRUCTION COURSE

For details concerning the second annual course of instruction for orthoptic technicians, the first part of which will be given at Nasson College, Maine, June 25 to August 27, 1949, write to the American Orthoptic Council, 1605 22nd Street, N.W., Washington 8, D.C.

MISCELLANEOUS

TO BE ACADEMY GUEST

Sir Stewart Duke-Elder has accepted an invitation to be the guest of honor of the American Academy of Ophthalmology and Otolaryngology and will attend the October meeting.

WANTED SERIES I AND II OF THE JOURNAL

The JOURNAL would like to purchase volumes 1 and 2 of Series I of the American Journal of Ophthalmology and volumes 1 to 7 of Series II. Address communications to the Ophthalmic Publishing Company, 664 North Michigan Avenue, Chicago 11, Illinois.

NEUROMUSCULAR CONFERENCE

The 21st semiannual conference in neuromuscular anomalies of the eyes was held at the Children's Memorial Hospital, Chicago, on May 1st to 6th by Dr. George P. Guibor and Dr. Charles Bahn.

SOCIETIES

ORTHOPTIC GROUPS MEET

The meeting of the midwestern group of the American Association of Orthoptic Technicians was held in Chicago on April 30th and May 1st, at the Eye Clinic Northwestern University Medical School.

The eastern group met in Rochester, New York, on May 2nd and 3rd. The program meeting was held at Strong Memorial Hospital, and a tour was conducted through the Bausch & Lomb factory.

On May 2nd and 3rd, the southern group met at the Henry Grady Hotel in Atlanta, Georgia.

NEW YORK ALUMNI MEET

The New York University College of Medicine-Bellevue Hospital Ophthalmological Alumni Association held its alumni meeting at the New York University College of Medicine on April 18th, 19th, and 20th.

LOS ANGELES OFFICERS

The Los Angeles Society of Ophthalmology and Otolaryngology has elected the following officers for 1949: President, Dr. Warren A. Wilson; secretary-treasurer, Dr. Victor Goodhill; chairman of section on ophthalmology, Dr. George Landegger; secretary of section on ophthalmology, Dr. Harold B. Alexander; chairman of section on otolaryngology, Dr. Alden H. Miller; secretary of section on otolaryngology, Dr. Leland R. House.

The meetings are held at 6 P.M. on the fourth Monday of each month from September to May at the Los Angeles County Medical Building, 1925 Wilshire Boulevard.

MILWAUKEE PROGRAM

The March meeting of the Milwaukee Oto-Ophthalmic Society was held at the Milwaukee County Hospital. The department of otolaryngology presented two papers, "Bilateral facial paralysis," and "Aberrant lingual thyroid gland." Members of the department of ophthalmology spoke on: "Symposium on angiograms: Aneurysm of the circle of Willis," and "Bilateral homonymous hemianopia." The discussion was in charge of the department of neurosurgery.

RENAME PALESTINE SOCIETY

The Palestine Ophthalmological Society (chairman, Dr. Aryeh Feigenbaum, 15 Abyssinian Street, Jerusalem; secretary, Dr. E. Sinai, 9 Bialik Street, Tel-Aviv) has been renamed the Israel Ophthalmological Society.

HOLD JOINT MEETING

The 91st meeting of the Reading Eye, Ear, Nose, and Throat Society was held jointly with the Wilkes-Barre Ophthalmological Society. Clinics were held at the Jefferson Hospital Medical School, Philadelphia, under the direction of Dr. William T. Hunt, Jr., assistant professor of ophthalmology, Jefferson Medical College.

Papers presented at this meeting were: "Physiology of the extraocular muscles," Dr. Arno E. Town; "Detachment of the retina," Dr. James S. Shipman; "Field defects and intracranial pathology," Dr. William T. Hunt, Jr.; "Central field changes as shown by angioscotometry," Dr. N. A. Karakashian; "The treatment of gliomas by radium applicator," Dr. Joseph Waldman; "Dacryocystitis," Dr. Alvin W. Howland; "Ocular therapeutics," Dr. Irving H. Leopold; "Secondary glaucoma," Dr. Carroll R. Mullen.

CÓRDOBA SOCIETY OFFICERS

The Sociedad de Oftalmologia de Córdoba (Argentina) has elected the following officers to serve for the next two years: Chairman, Dr. Roberto Obregón Oliva; secretary, Dr. Alberto Urrets Zavalía (hijo); treasurer, Dr. Roque A. Maffrand; directors, Dr. Rodolfo Laje Weskamp and Dr. Marcos H. de Anquín.

All correspondence should be directed to the secretary at 27 de Abril 255, Córdoba, Argentina.

Secretary and Registered Offices:

A. E. Ayling, Friars House, 39-40-41, New Broad Street, E.C.2

The Company was formed in 1916 with the object of establishing a representative Journal of Ophthalmology for the British Empire. For this purpose the Company has incorporated the three existing Ophthalmic publications known as

The Royal London Ophthalmic Hospital Reports, The Ophthalmic Review, and *The Ophthalmoscope.*

Ophthalmologica

International Journal of Ophthalmology
Journal international d'Ophtalmologie
Intern. Zeitschrift für Augenheilkunde

It is the task of "Ophthalmologica" to advance our knowledge in Ophthalmology by stimulating international co-operation. We publish:

1. Papers in English, German and French.
2. Reviews. One or more subjects of Ophthalmology will be reviewed every month, so that the reader obtains a comprehensive survey of all the publications which have appeared during the past year.
3. Notes on practical questions. These columns are to be devoted to short interesting observations on cases occurring in everyday practice. They will appear in concise form, perhaps accompanied by an illustration.
4. Reports about the activities of Ophthalmological Societies.
5. Book Reviews. News.

Look what's happened to Univis Trifocal Rx's

1938...
2,106 pairs
Now a Total of...
310,156 pairs
have been prescribed

1938

in the last 10 years!

Why?

The growth in the use of trifocals, especially in the last 10 years, has been substantial. It has come about because: (1) Design and manufacture have improved; (2) There is a better understanding of when to prescribe and how to fit; (3) There is an increasingly more thorough analysis of the patient's near seeing problem; (4) The growing amount of clinical data for study furthers practitioners' confidence.

What now?

There is a great number of bifocal wearers today who would benefit by the prescription of trifocals—about *half of them*, as a matter of fact! This conclusion is based on the fact that in 1947, about 50% of all Univis multifocals prescribed were 1.75D or greater in the reading addition. Yet, only 1.5% of these were trifocals. It's reasonable to assume that the others in that category are potential trifocal wearers, discounting any other individual reasons why bifocals may be more advisable.

What now? Look for an increasingly greater number of trifocal prescriptions from every section of the country!

SUGGESTIONS FOR THE SURGICAL MANAGEMENT OF STRABISMUS*

THE FOURTH SANFORD R. GIFFORD MEMORIAL LECTURE[†]

LAWRENCE T. POST, M.D.
Saint Louis, Missouri

It was with great pleasure that I accepted the invitation of your society to deliver one of the annual Sanford R. Gifford lectures. "Sandy," as he was affectionately called, was a man whom I was proud to consider an intimate friend ever since we had struggled together at one of the early American Board of Ophthalmology examinations.

This opportunity to pay my small tribute to Dr. Gifford is one that I could not refuse and my sole regret is that this appreciation cannot be a more impressive one. Distinguished son of a distinguished father, Dr. Gifford made an enviable place for himself in the history of ophthalmology in America. It is hard to select his greatest contribution, but probably his textbook would be so considered as it was ideal in its field, broadly informative, accurate, and, above all, readable—a quality characteristic of all of his writing, one so eminently desirable and so seldom achieved.

He was an outstanding ophthalmologist, a charming, cultured gentleman, and a loyal friend.

When asked to present this talk, I recalled that the first Gifford lecture was by Dr. Francis Heed Adler on the etiology of strabismus. It occurred to me that a consideration of the practical side of the subject of strabismus might serve as a humble complement toward completion of the idea, although I must at once admit that this essay can cover only a few general suggestions on a big subject.

I. THE HISTORY

The most important etiologic factor is heredity. It occurs so frequently as to be the rule rather than the exception.

Another important historical factor is age of onset. In those patients in whom strabismus occurs early, roughly before the age of two years, there is almost always an anatomic basis and, in my experience, they are less prone to develop fusion postoperatively than those who develop strabismus later in life. This, I believe, is due to the fact that the children who develop strabismus later probably had already acquired some fusion before the deviation set in and the newly found fusion is merely a reëducation.

On the other hand, my associate, Dr. R. G. Scobee, has noted the acquisition of fusion in 8 of 10 infants with congenital strabismus who were operated on at the age of one year. He argues that given a mechanism permitting alignment of the eyes, fusion will usually develop and aid in holding the eyes straight.

He also believes that 90 percent of all strabismus appearing before the age of six years has an underlying anatomic basis, his point being that check ligaments, muscle slips, and abnormal insertions are found in 90 percent of the cases of strabismus (whereas they are never found in anatomic dissections of normal eyes) and that anatomic anomalies

act as important underlying primary causes when associated with other etiologic factors.

II. The Examination and Procedure

1. A careful study is made of the fundi after full dilatation of the pupils. Abnormalities are noted and a gross estimate of the error of refraction is made. This dilatation is not for refraction but merely for the fundus examination. Atropine is used 3 times a day for 4 days before refraction.

2. Complete occlusion of the fixating eye is used to establish alternation. Elastoplast is a convenient material for this.

3. Glasses that contain full correction as measured under atropine are prescribed for constant wear. Too often ophthalmologists reduce this strength and thereby lose the advantage of full relaxation of accommodation and consequently the greatest relief of overconvergence.

4. As soon as coöperation permits, vision is taken with and without correction.

5. Near point of convergence is measured.

6. Angle Kappa is determined for each eye separately. The patient rests the chin in the cups on each side of the central standard, alternately, and fixates the central target on the perimeter with the fixing eye exactly over the finder. The reflection on the cornea of a flashlight moved along the arm of the perimeter is watched until it is exactly centered over the pupil, and the number of degrees of arc measured from the reflection of this flashlight to the center of the target equals the angle Kappa. If to the right for the right eye, it is plus, and if to the left, it is minus. Just the opposite pertains for the left eye.

7. Heterotropia is estimated by Hirschberg's method in infants. This method depends on the amount of displacement of the corneal image of a light, such as from a small bulb, on the cornea of a deviating eye while the patient fixates the light with the other eye. About 15 degrees of deviation may be estimated if the reflex lies at the pupillary margin of a 4-mm. pupil; if about

half way between the pupillary margin and the limbus, the strabismus is about 30 degrees; if at the limbus, it is about 45 degrees.

8. Heterotropia is actually measured on the perimeter in children old enough to coöperate. The nose is placed in the midline of the perimeter and when the light from a flashlight moved along the perimeter arm is reflected on the exact center of the cornea of the deviating eye, the arc degrees are measured. Each eye is tested in turn; first, without glasses—with each eye fixing; then with glasses—with each eye fixing.

9. Heterotropia is also measured by screen and parallax.

10. Primary and secondary deviations are measured with prisms at this time. The patient is directed to fixate the light at 20 feet, first without correction and then with correction, with one eye and then with the other. Such prisms as are necessary to eliminate the movement when they are held before each eye in turn measure the primary and secondary deviations. In a similar manner tests are made at 13 inches. Ductions and versions are estimated and recorded on charts, but not measured in degrees, primarily to determine the vertical elements. Measurements in degrees in extreme positions of gaze have been found to be so variable that they have been discarded as more misleading than helpful.

III. Treatment

As early as possible, usually at about the age of 4½ years, orthoptics are instituted. An attempt is made to determine the nature of the correspondence and, if abnormal, to break it up and restore normal correspondence. Frequently orthoptics are impossible because of the remoteness of the patient's home, in which case, if the wearing of glasses, plus occlusion, does not accomplish straightening of the eyes, surgery is routinely recommended.

Although fusion is undoubtedly desirable because of some advantage of stereopsis in life, its greatest value is in preventing later

deviations which are much more prone to occur if fusion is absent.

It is fortunate that the majority of obvious muscle anomalies are in the horizontal field and since one general rule is to attempt to correct the principal defect first, the surgery of the horizontally acting muscles is usually the first to be done. This is the saving factor for many who do not analyze their cases carefully but correct only the horizontal deviation. They often get a good cosmetic effect. It is true also that vertical anomalies are less noticeable than horizontal.

It has been observed that the greater defect should receive first attention. It is important to remember that correction of the lateral deviation in cases in which there is also a vertical deviation may either increase or decrease the latter, depending on the muscles involved. For example, if a vertical rectus is involved, the deviation will be greater after correction of esotropia because returning the eyes to the primary position will bring them nearer the field of the maximum action of the vertical recti; whereas, if the difficulty is with an oblique, the effect of the correction of esotropic abnormality will be an apparent lessening of the strabismus caused by the abnormalities of an oblique muscle. Correction of an exotropia will act similarly but in a reverse manner.

If a cosmetic result is the surgeon's primary goal, a careful study of the angle Kappa is most important. The ratio of positive angle Kappa to negative angle Kappa is about 50 to 1. The average for each eye is about 5 degrees. Obviously a plus angle makes a convergent strabismus appear less than it actually is. Some people have such high plus angle Kappas that they actually appear to have an exotropia.

A surgical undercorrection in such a case will be compensated for cosmetically to whatever extent a plus angle Kappa may have been present before operation and, similarly, overcorrection is desirable for appearance sake, not for function, in cases of exotropia with a positive angle Kappa because

the positive angle will make the exotropia appear greater than it actually is. However, it must be emphasized that this has no bearing on the development of fusion.

In choosing whether one eye or two are to be operated on in cases of lateral tropias, the following should be noted. Both eyes should be operated on if there is alternation, and a bilateral recession of the medial recti may be done if necessary if the near point of convergence is small; if larger than normal, more than 4 cm. from the bridge of the nose, and a secondary convergence palsy is present, not more than one medial rectus should be recessed. It is also true that other tests may indicate a contracture of a medial rectus as by abnormal check ligaments, muscle slips, or abnormal tendon insertions. These must be severed, as simply working on the medial recti tendons alone will be insufficient.

If the deviation is greater for near than for far in esotropia and esophoria, there is usually considered to be a convergence excess; but if greater for far than for near, a divergence weakness is presumed to exist. The near point of convergence is, however, a better gauge of the desirable surgery. In the former case, bilateral recession of the interni is usually indicated and, in the latter, a bilateral advancement or tuck of the lateral recti may theoretically be best, but it is seldom performed and the aforementioned considerations should weigh heavily in the decision as to the type of surgery. Any defective muscle must be investigated for possible abnormal check ligaments or other restricting abnormalities.

To be borne in mind is the help furnished by hypermetropia in combatting an overcorrection of esotropia. For example, presuming a high hypermetropia and a surgical overcorrection of a convergent strabismus, it is often possible to get a good result, including fusion, by prescribing an undercorrection of the hypermetropia, thus stimulating convergence.

Similarly, full correction, or even a little

overcorrection, will often compensate for surgical undercorrection.

In like manner, in cases of exotropia or exophoria, if the deviation is greater for near than for far, the condition is supposed to be a convergence weakness and, if greater for far than for near, it is supposed to be divergence excess. In the former case, resection of one medial rectus and recession of the lateral rectus in the same eye or a bilateral resection of the medial recti may be done and, in the case of divergence excess, bilateral recession of the lateral recti is to be done.

All of the factors mentioned and others also must be evaluated to determine the best remedial surgery in the given case. To reiterate, of the above considerations the near point of convergence is probably the most important.

Several consoling facts in the surgery of strabismus may be mentioned. Parents do not often demand a perfect result, being satisfied with a good postoperative appearance. Fusion and its value, unless stressed by the surgeon, mean little to them or to the child. Lastly, third-degree fusion is often obtainable without an exact correction of the deviation, since the innate fusion desire, plus fusion training, may bring this about.

The technique of the surgery is not considered of as great importance by me as is the diagnosis that indicates what should be done surgically, provided that: (1) the muscles are so sutured that they will be well spread out in their new positions and will not slip, (2) anatomic anomalies and check ligaments, when found, are cut, and (3) muscle sheaths are not unnecessarily removed.

It must be understood that I do not think that it is always possible to determine just what surgical procedure will be best until the patient is under anesthesia and the muscles inspected. Observation under anesthetic should then include (1) noting the difference in the amount of the deviation at that time from that before operation, (2) the action of the eye when pressure is made in the canthus opposite that of the deviation,

(3) the condition as regards check ligaments and intermuscular septa and insertions, and (4) the elasticity of the severed muscles in order to determine the extent of the surgery to be done on each.

IV. SURGICAL TECHNIQUE

My technique for both recessions and resections is as follows: The tendon of the muscle to be recessed is exposed by a 10-mm. curved incision over the tendon insertion. Tenon's capsule is lifted at the upper or lower border of the muscle and snipped. A muscle hook is introduced under the tendon and brought out at the opposite border after another snip is made in the capsule at the point of exit of the hook.

The muscle is secured by one arm of a double-armed, 3-0, plain catgut suture introduced at the junction of the upper and middle thirds of the tendon and carried through the middle thickness of the tendon to the border and then looped behind the muscle to its center, the needle being brought out proximal to the suture and passed through the loop of the suture and drawn taut.

The other half of the double-armed suture is introduced similarly through the lower third of the tendon. The tendon is cut very close to its insertion. It is then held away from the globe, and the conjunctiva and all check ligaments and abnormal bands between the recti are cut with sharp scissors until the muscle retracts freely into the orbit, care being taken not to strip the muscle sheath away from the muscle. It is then secured by suturing the two free ends of the tendon to the globe at the desired points at least 5 mm. apart. A surgical knot is used so that there will be no slipping as the knot is tightened.

Closure of the conjunctiva is with the remnants of the catgut. Three sutures are used. These are later absorbed or fall out. This is much simpler than the removal of nonabsorbable sutures in intractable children.

Resection is performed in a similar

manner. The suture is placed in the tendon at the desired distance from the insertion, and the free end of the tendon between the suture and the insertion is excised. It is wise not to cut the lateral and other attachments.

One point is of utmost importance and, although often mentioned, is not sufficiently observed. It is the cutting of check ligaments. These bands extending to the orbital wall, especially large and prominent from the medial recti, if not carefully severed will usually nullify the effect of surgery on these muscles. The usual illustrations suggest that they are single sheets, but actually they almost never occur singly but more often radiate from the muscle sheath in fan-shaped planes.

Abnormal muscle slips, especially between the recti, must also be looked for and, if found, must be severed for a like reason. The surgeon should be sure that the muscle will retract freely into the orbit after it has been cut from its insertion and that no check ligaments remain. For a comprehensive discussion of the importance and handling of these ligaments, I would refer you to a recent paper by Dr. R. G. Scobee,[1] who has also pointed out the value of making pressure in each canthus to determine the binding effect of each rectus. If firm adhesions or constrictions exist, the eye will be pushed back and will not turn freely. This may be an important guide to surgery.

Another point, previously mentioned, is whether or not under anesthesia the contracted muscles relax and the eyes appear straighter than before anesthesia. If they do, there are less apt to be strong contractures. In those cases in which the eye rotates readily upon pressure of the strabismus hook or the convergence is much less under anesthesia, the strabismus is probably on an innervational basis and surgery, especially advancement, must be most conservative or an overcorrection may result.

In cases of alternating convergent squint, if the patient uses his right eye when looking left and his left eye when looking right, there is usually no overactivity of the medial recti and the convergence near point may even be remote. The general rule that only one medial rectus should be recessed in such cases must be followed or a divergence may result. On the other hand, if a convergent alternator uses the right eye when looking right and the left eye on looking left, abduction is usually good and the medial recti are habitually overacting and bilateral recessions of these muscles can be done safely.

I concur in Payne's[2] recommendation that a patient with what appears to be paralysis of a lateral rectus should have a full resection of the apparently paralysed muscle and a recession of the antagonist rather than a Hümmelsheim operation as the first procedure because often such surgery will show that the muscle was not truly paralyzed, and the more elaborate operation of splitting the superior and inferior recti and utilizing their halves to aid the nonacting muscle may prove unnecessary.

Surgery of the obliques is occasionally indicated. The question then arises whether the weak oblique should be advanced, as has been done very successfully by McLean and others, or the yoke muscle weakened. This latter has been the method I have used, but such good results are claimed for working on the weaker muscle that I am not convinced that my method is the better procedure.

A point to be made is that the section of the inferior oblique should be made near its insertion and not, as often recommended, at its origin. The reason for this is that there is much variation in the insertion and that the suspensory ligament of Lockwood acts as a secondary origin and, since this is distal to the part sectioned in tenotomy near the origin, there is often very little accomplished by the operation.

Fink[3] has brilliantly pointed out numerous variations in the insertions of the inferior oblique. The insertion can be exposed without sectioning the lateral rectus, which is pulled upward by an assistant who reaches outward below the tendon of the lateral rectus and hooks the tendon of the inferior

oblique upward and medially before it is severed.

The superior oblique may be reached either by sectioning the superior rectus and hooking the superior oblique downward, opening its sheath horizontally and cutting the tendon in its sheath, or, as Berke[4] has advocated, without cutting the superior rectus tendon. If more effect is desired, a few millimeters of the tendon can be resected. I have found that sectioning of the superior rectus makes the operation much simpler.

The problem of exophoria-exotropia is a constantly recurring one. Exercises sometimes develop good fusion and comfort when discomfort has been noted. The tendency, however, as time goes by, is toward increasing divergence and finally results in failure of fusion from disuse. Surgical correction is simple and usually effective. Principles already outlined should govern the type of surgery. I have had consistent success with this procedure.

Conclusion

There should be a thoughtful and complete study of each case of strabismus before surgery and the role of the vertical recti in producing the defect should be carefully analyzed and a two-stage operation performed in cases in which both lateral and vertical deviations occur.

BETA IRRADIATION OF THE EYE*

WILLIAM F. HUGHES, JR., M.D.
Chicago, Illinois
AND
CHARLES E. ILIFF, M.D.
Baltimore, Maryland

Recent reports and discussion of the value and dangers of irradiation of the eye with the beta rays of radon have been both enthusiastic and pessimistic.[1-4] The present uncertainty can be attributed to many factors, among which may be mentioned: (1) Variability in dosage and technique of application, with too little attention being paid to the characteristics of the irradiation used, the distance of the applicator from the eye, localization of the area to be treated, and possible cumulative effects; (2) ignorance of the differential sensitivity of the normal tissues of the eye and those tissues which are to be destroyed by irradiation; and (3) difficulty in comparing the results of beta treatment with untreated controls. Often the beta irradiation clinic becomes a convenient spot to which hopeless cases can be referred regardless of theoretical or practical justification.

In this paper, the various techniques and effects of beta irradiation will be discussed in an effort to arrive at a selection of suitable cases for treatment, and to utilize a dose sufficiently large to destroy undesirable tissue without undue damage to the normal structures of the eye. In addition, we will report some preliminary experiments on the use of beta irradiation following chemical burns of the eye, especially in regard to vascularization of the cornea.

TECHNIQUES FOR THE USE OF BETA IRRADIATION

The Burnam applicator, which contains a concentrated source of radon in a single glass bulb, has been described previously.[1, 5] The alpha particles or helium nuclei are completely absorbed by the soda glass bulb containing the radon. The beta particles or electrons are directed through a 4-mm. opening at the end of a brass tube of walls 2 mm. in thickness. The gamma rays, comparable to hard X rays, are emitted simultaneously with the beta particles but only in comparatively low concentration. According to Failla and others,[6] radon emits 96.5-percent beta and 3.5-percent gamma in terms of electrostatic units of ionization.

From a bulb such as the Burnam applicator, the center of which is 2.5 mm. from the tissue, 75.2 percent of the irradiation is absorbed within the first millimeter of tissue, 93.7 percent within the first 2 mm., 96.1 percent within the first 3 mm., and 98.9 percent within the first 5 mm.

The ratio of beta to gamma varies at different tissue depths as follows: at 1 mm. = 88-percent beta; at 2 mm. = 78.5-percent beta; at 3 mm. = 67.6-percent beta; at 4 mm. = 55.5-percent beta; and at 5 mm. = 43-percent beta. Therefore, it is possible to give therapeutically useful doses of beta without significant gamma irradiation which might damage the lens or deeper structures of the eye.

Because of the unavailability of radon in many localities, a radium applicator for ocular use has recently been described.[7] Although the applicator contains 50 mg. of radium, the effective output of beta particles is only about 30 mc. Such a relatively low output necessitates prolonged treatment times, and because of this a mechanical holder is desirable.

This applicator is apparently satisfactory for most conditions, but the source is not

sufficiently localized and concentrated for use in the obliteration of corneal vascularization. Also, the safety ratio between the output of beta and gamma is reduced by almost half. This type of criticism can be applied to many sources of beta radiation in which the mass itself filters out a significant number of the beta particles.

DOSAGE

One gram of radium is equivalent to one curie or 1,000 mc. of radon, a gaseous emanation of radium which emits radiations identical to those of radium. The dose of beta particles is dependent on the amount of radon and the duration of treatment, and can be calculated as follows:

$$\text{No. secs. exposure} = \frac{\text{No. gram secs. desired} \times 1,000}{\text{No. millicuries of radon}}$$

(or)

$$\text{No. mins. exposure} = \frac{\text{No. millicurie minutes desired}}{\text{No. millicuries of radon}}$$

For conversion:

No. gm. secs. $\times$ 16.66 = No. millicurie mins.
No. gm. secs. $\times$ 0.278 = No. millicurie hrs.

The intensity of irradiation varies inversely with the square of the distance of the applicator from the target. Therefore, a slight variation in distance results in a large difference of effective dose. In addition, with the so-called "spray technique" in which the applicator is held from 1 to 3 mm. above the tissue and is moved slightly back and forth, there is an uneven and uncertain distribution of the total dose over a poorly defined area.

For these reasons during the past two years treatments have been given by placing the applicator in contact with the lesion. The dosage for such contact therapy varies between 3 and 5 gram seconds per treatment. Ordinarily, treatments are not administered more frequently than every two weeks to the same area in order to avoid cumulative effects. In all initial treatments, and especially in children, even smaller doses should be given to avoid undue reactions in

hypersensitive individuals. The rabbit eye is more resistant to the effects of beta particles than the human eye, tolerating approximately three times the dose for human beings.[8, 9]

THE ACTION OF IRRADIATION ON TISSUES

Irradiation has no effect on tissues unless it is absorbed. In addition, the intensity of the effect is directly related to the amount of effective quantum energy, an inverse function of the wave length, at the site of absorption. It is generally agreed[9-12] that the biologic actions of various types of irradiation on the individual cell and supporting structure are similar. When the beta particles or high speed electrons strike a cell, changes are produced in both the cytoplasm and nucleus associated with ionization of the tissue. Large doses cause immediate death of the cell, perhaps by mechanical rupture of the structural portions of the cell and chromosomes. This is particularly true of beta irradiation in which 75 percent of the dose is absorbed within the first millimeter of tissue, producing a more concentrated number of "hits" and ionization than with X ray or gamma rays, which are absorbed more diffusely and deeply in the tissues.

Following smaller doses of irradiation, histologic changes are well demonstrated in the corneal epithelium.[8, 13] A few hours following a small dose of ultraviolet or beta irradiation, normal mitotic figures disappear from the basal layers of the epithelium. With somewhat larger doses, a small proportion of cells develop nuclear fragmentation, the chromatin material sometimes assuming the configuration of abnormal mitoses.

In agreement with experiments using other types of irradiation, the resting cell seems to be relatively resistant to damage. However, the cells which later develop abnormal mitoses and nuclear fragmentation are probably in a specially sensitive state at the time of exposure; namely, a premitotic or very early stage of prophase.[11] This may explain why rapidly proliferating tissues are

especially sensitive to irradiation—embryonic tissue, the tissues of young growing children, germinal epithelium, and certain neoplasms.

As will be pointed out later, rapidly proliferating endothelium of capillaries growing into the cornea can be inhibited by a smaller dose of beta than that required to obliterate an already formed vessel. In order to catch as many cells as possible in the sensitive premitotic stage, most radiotherapists use repeated small doses to destroy undesirable proliferating tissue, thereby reducing the amount of damage to less sensitive normal tissue.

Clinically, nuclear fragmentation in the corneal epithelium produces a superficial punctate erosion stainable with fluorescein. Larger doses of beta irradiation readily cause necrosis and disappearance of corneal stromal cells, thus emphasizing the need for caution in radiation treatment of any condition directly over the cornea, especially if there has been some loss of stromal cells previously from the disease process (recent chemical burn, corneal ulcer, and so forth).

Irradiation also causes a swelling of collagen,[10] one of the important structural components of the corneal stroma. Since a significant proportion of beta does not penetrate deeper than the cornea or sclera, doses sufficiently large to cause the perforation of a rabbit's cornea can be given without the development of cataract. A few rabbit eyes received 12 gram seconds of radon every 2 weeks for 8 months without the development of cataracts.[8] Clinically, we have not seen any radiation cataracts from radon treatment over the course of 10 years, and this experience is corroborated by Ruedemann.[2]

In agreement with almost all radiologists, we have found no evidence of stimulating action following irradiation. In fact, all regenerative processes seem to be retarded following the use of beta; namely, regeneration of the corneal epithelium, proliferation of new stromal cells, and vascularization of the cornea.[8]

The well-known cumulative effects of radiation apply to beta radiation of the eye. The interval during which a second application of beta is additive to a previous dose varies directly with the size of the dose. In general, however, cumulative effects are obtained if two therapeutic doses are given within a period of two weeks.

RADIOSENSITIVITY

Since the principle underlying all radiotherapy consists of a differential sensitivity of the diseased tissue to be destroyed and the normal surrounding structure, the relative radiosensitivity of various cells becomes important.

Desjardins[14] listed these in order of diminishing sensitivity as follows: lymphoid cells, polymorphonuclear and eosinophilic leukocytes, epithelium, endothelium, connective tissue, muscle, bone, and nerve.

Other factors which increase radiosensitivity are as follows:[9] undifferentiation and immaturity of the cell, state of activity (premitotic), active metabolism (related both to oxygen consumption and growth), and increased blood supply (in inflammatory conditions).

EFFECTS OF BETA IRRADIATION TREATMENT OF CONDITIONS INVOLVING THE GLOBE

The dramatic responses of certain bulbar conditions to the application of beta irradiation have been described elsewhere[1, 2] and will not be repeated here except to point out *the reasons for the outstanding successes* and possible explanations for the failures.

VERNAL CONJUNCTIVITIS

The excellent therapeutic response following the use of beta irradiation in both palpebral and limbal forms of vernal conjunctivitis has been amply demonstrated by many clinicians. In early cases, the papillae consist of lymphoid cells, young fibroblasts, and blood vessels, and these elements are very radiosensitive. However, old "pavement-stone" vegetations which contain areas of hyaline degeneration and old fibrous tissue are more resistant. Successful radiotherapy

of vernal conjunctivitis also reduces the number of recurrences.

Papillomas

Papillomas of the lids, conjunctiva, and limbus usually respond dramatically to beta irradiation. Since an intraepithelial epithelioma of the limbus spreads superficially over the cornea, this neoplasm can be destroyed by beta irradiation without damage to the underlying normal corneal stroma. Of course, beta cannot be used for any tumor which extends into the eye or orbit because of its lack of penetration.

Angiomas

Except for the nevus flammeus or port-wine stain, angiomas of the lids, conjunctiva, and caruncle are very radiosensitive.

Vascularization of the cornea

The possible importance of the ingrowth of blood vessels into the cornea to relieve anoxemia or remove toxic inflammatory products cannot be evaluated at present. However, several undesirable features of corneal vascularization may be listed.

1. Reduction in the transparency of the cornea. "Shadow vessels" ordinarily cause little reduction in vision. However, Spicer has described a late secondary opacification around such vessels giving the appearance of "lines of clearing" and resulting in a significant decrease of visual acuity.

2. Following extensive injuries of the corneal stroma including the limbus, there is a pronounced tendency toward the ingrowth of blood vessels, accompanied by a pterygiumlike tissue over the surface of the cornea. A nodule of granulation tissue may form on the cornea, persisting as a thick scarred cornea of uneven surface.

3. Many heavily scarred and vascularized corneas remain chronically irritated, edematous, and show evidence of retarded healing.[15]

4. A heavily vascularized cornea makes a poor candidate for later keratoplasty.

Beta irradiation has been used clinically to prevent or more often to obliterate corneal vascularization. To determine the most effective technique for this purpose, we have applied beta to the vascularization of rabbit corneas which followed intracorneal injection of sodium hydroxide.

Technique of experiments

Corneal vascularization was induced by the intracorneal injection of 0.05 cc. or 0.1 cc. of N/20 sodium hydroxide. The most marked and consistent vascularization was produced when the opaque area of injection touched the limbus. When the injected area was located centrally and was surrounded by a zone of clear cornea, vascularization was minimal.

On the other hand, extravasation of the sodium hydroxide into the region of the limbal vessels resulted in ischemic necrosis of this region, and subsequent vascularization of the cornea usually arose from the intact limbal vessels at the edge of the lesion. The severity of the important corneal symptoms was graded numerically according to the following scale of maximal values:

Corneal Opacity: intensity plus 4 × area in millimeters = total grade.
Corneal Vascularization: millimeters of limbal circumference from which vessels enter cornea × millimeters of distance the vessels enter the cornea.

Comparison of treated and untreated areas was made either between two separated areas in the same cornea (0.05 cc. of N/20 sodium hydroxide injected in each area), or more often between two eyes of the same animal (0.1 cc. of N/20 sodium hydroxide injected in each eye).

Since it was technically impossible in most instances to produce two exactly similar lesions for comparison, some allowance was made in Table 1 for the fact that the most severe opacity was usually treated. This was done as follows: (a) the initial reading of the corneal opacity to be treated was given a plus value and the control area a negative value; (b) the final reading of the treated

cornea was given a negative value and the control area a positive value; and (c) a final value to determine any possible effect of treatment was obtained by taking the algebraic sum of the original difference and final difference between the treated and control areas. A plus value would therefore suggest a beneficial effect of treatment and a minus value a detrimental effect.

vessels, as illustrated in Figure 1. However, because the area covered by the applicator was only 4 mm. in many of the eyes treated in this manner, large trunk vessels would pass between the sites of treatment and enter the cornea, thence fanning out and thoroughly vascularizing the entire burned area.

Efforts were made to obliterate already

Eyes Nos. 1, 2, 3, 4, 8, 9, 10, 11 received two areas of injection in each cornea of 0.05 cc. of N/20 NaOH each. Two areas compared in a single eye.
Rabbits Nos. 5, 6, 7, 12 received a single injection of 0.1 cc. of N/20 NaOH in each cornea. Two eyes compared.
Burnam applicator and Lucite contact glass used (8), the glass bulb containing radon being 6 mm. above the area treated.

Results

1. Treatment over lesion (table 1). Application of varying doses of beta at varying intervals directly over the area of corneal involvement had little effect on the ultimate corneal opacity, but, if anything, made the pannus more intense.

2. Contact therapy without lucite holder. In 21 eyes, the Burnam applicator without lucite holder was placed in direct contact with the limbus adjacent to the area injected 24 hours previously. An average number of 4 applications at one sitting was performed, the dose for each site ranging from 6 gram seconds to 24 gram seconds. This single treatment with beta had little effect on the corneal opacity. A dose of 12 gram seconds was sufficient to inhibit the ingrowth of

formed vessels by direct application of the Burnam applicator at the source of the vessels at the limbus. A dose of 6 gram seconds was insufficient to obliterate even superficial loops of vessels, 12 gram seconds effectively obliterated superficial vessels of moderate size, and 18 gram seconds occluded deeper vessels. Doses of 18 to 24 gram seconds also seemed to cause some additional necrosis of the already injured corneoscleral tissue, a few eyes developing perforations at the site of heavy treatment and chemical necrosis. Mulberrylike elevations of granulation tissue on the surface of the cornea could be reduced by 12 gram seconds applied directly over the area. However, the obliteration of large trunk vessels by beta could only be accomplished at the expense of excessive
Fig. 1 (Hughes and Iliff). *Right eye* (pictures on left). Intracorneal injection of 0.1 cc. of N/20 sodium hydroxide treated one day later with 12 gram seconds of beta irradiation at each of three sites on the limbus adjacent to the involved area. Photographs (top to bottom) at 15 days, 21 days, and 29 days after injection. *Left eye* (pictures on right). Untreated control. Photographs (top to bottom) at 15 days, 21 days, and 29 days after injection.

scleral necrosis, and could have been more easily accomplished by means of electrolysis or cautery.

3. Spray therapy at limbus with lucite holder (table 2). Because of the great tendency for vessels to slip between and around the sites of beta application, a lucite holder was used in the following series of experiments in order to provide a wider area of exposure (11 mm.) and some overlapping.

The radon bulb was held 6 mm. above the tissue with this holder. In this small series

of experiments, little significant effect of beta on the residual corneal opacity and pannus could be detected after "spray therapy" over the limbus. However, the maximal intensity of pannus was significantly lower in 7 eyes which received an application of 75 gram seconds over two limbal areas 24 hours after the injection of sodium hydroxide.

Several striking results were seen repeatedly following the use of beta in these experiments: (a) A dose of 6 gram seconds held 6 mm. over the limbus prevented the ingrowth of superficial but not of deep

a control for the beta experiments previously described, dry ice was applied for 15 seconds to the sclera adjacent to the area of corneal opacification produced by the injection of 0.1 cc. of N/20 sodium hydroxide two days previously. In 5 rabbits followed for 52 days, the treated eyes showed an average maximum pannus of 36 compared with a grade of 26 for the untreated eyes, and the average residual vascularization after 52 days was 9 points worse in the treated eyes. No effect was noted on the intensity of the corneal opacification. The effect of beta, therefore, either has a more

vessels, and 12 gram seconds largely prevented deep vascularization of the cornea. (b) Normal limbal vessels were unaffected by doses of 12 gram seconds, although 24 gram seconds produced ischemia and edema. (c) With single small doses insufficient to prevent corneal vascularization indefinitely, a delay of from 2 to 3 weeks in vascularization was noted. (d) Budding loops of vessels growing into the cornea could be stopped at any point by beta, the ends of the vessels becoming bulbous, tortuous, and associated with small blood lakes.

4. *Effect of dry ice on corneal vascularization.* The application of dry ice to tissue is a good method of producing cellular destruction without much structural alteration. As

specific effect on the proliferation of capillary endothelium, or a more prolonged action.

Summary

With rabbit corneas previously exposed to sodium hydroxide, the use of beta irradiation was most effective in the reduction of granulation tissue masses on the surface of the cornea and in the obliteration of small superficial blood vessels crossing the limbus.

Vascularization of the cornea could be prevented by the alert and judicious use of beta, the best results being obtained by covering a relatively wide area of the limbal sclera adjacent to and slightly beyond the limits of the cornea involved by the chemical

burn. The inhibitory effects of the irradiation lasted from 2 to 3 weeks. The relatively small doses of beta required to prevent the ingrowth of vessels must inhibit the proliferation of capillary endothelium, because clinical and histologic examination revealed no thrombosis of the vessels.

Once the vessels had become established in the cornea, larger doses of beta were required over the limbus to obliterate the vessels. Large trunk vessels were difficult to obliterate by beta treatment, and direct cauterization, electrolysis, or the use of diathermy current as advocated by Gundersen[15] would have been preferable.

As mentioned previously, not more than one third of the dose necessary for rabbits need be used for human eyes in whom a dose of 5 gram seconds contact therapy with the Burnam applicator over the sclera is sufficient to obliterate vessels.

The following clinical conditions associated with corneal vascularization have been treated with irradiation, the results of which have been reported favorable: (1) In conjunction with superficial keratectomy to prevent the revascularization of the cornea; (2) before and after keratoplasty in cases with heavily vascularized corneas; (3) chemical burns such as sulfur dioxide; (4) acne rosacea keratitis and other vascularizing keratitis of unknown etiology.

PTERYGIUM

Beta irradiation has been employed as a primary treatment for pterygium.[2] It is particularly useful in those cases of "malignant" pterygia which recur after surgical transplantation and are associated with marked vascularization.

INFECTIONS

The effects of roentgen irradiation in the treatment of inflammations have been reviewed well by Pendergrass and Hodes.[16] It is generally agreed that doses tolerated by the tissues are not bactericidal. Large doses apparently depress the defense mechanisms of the body, especially the reticuloendothelial system, and the most effective results are obtained by using no more than one fourth to one third of a skin erythema dose.

The reasons for the beneficial effects of small doses of X ray on acute inflammations are uncertain, but have been attributed to a destruction of leukocytes with liberation of proteolytic enzymes and antibodies,[17, 18, 19] liberation of antibodies from other sources, and the production of an active hyperemia.[16]

Chronic infectious granulomas, such as tuberculosis, respond favorably to somewhat higher doses of X ray, probably because of the radiosensitivity of epithelioid and giant cells which are replaced by fibrous tissue,[9] and perhaps because of the liberation of antibodies.

The relatively few attempts to treat pyogenic corneal ulcers with beta irradiation have been unsuccessful,[1] in some instances leading to perforation of the cornea. It may be that the concentrated character of this type of irradiation is unsuitable for acute infectious processes, that the dosage employed was too large, or that a beneficial hyperemia is impossible in the avascular cornea.

On the other hand, Woods[20] and Iliff[1] have reported that of 72 eyes with anterior ocular tuberculosis treated with beta irradiation, 52.8 percent were healed for at least one year, 38.9 percent were improved, and 8.3 percent were unimproved. Improvement in visual acuity of at least two lines occurred in 42 percent, vision was maintained at the same level in 46 percent, and decreased in 12 percent. No effect on recurrences of the attacks was noted. Because of the wide variation in the characteristics and ultimate prognosis of anterior ocular tuberculosis, statistical certainty that beta irradiation has been of value in this condition is impossible.

A few cases of ocular sarcoid have not responded favorably to beta treatment. Iliff[1] reported one case of blastomycosis of the outer canthus treated successfully with beta. Cases of pemphigus and lupus erythematosis have not responded.

CORNEAL SCARS

The ultimate clarity of the cornea following a condition which involves the stroma cannot be estimated accurately because of normal recovery powers including absorption of inflammatory exudate, subsidence of edema, disappearance of blood vessels, and regeneration of the corneal corpuscles. Such reduction in the size and intensity of the opacification is especially prominent in children, and the cornea may continue to become clearer for several years. For this reason, any results obtained in the treatment of corneal scars with irradiation should be interpreted cautiously. Although fibroblasts

Clinically also, beta irradiation was found to have no effect on old corneal scars of various types.[1] Doses sufficiently large to destroy old fibrous tissue destroy normal stromal cells and in fact retard normal regenerative processes. It is difficult to see how the use of beta on scarred corneas could have anything but a detrimental effect since there is no known stimulating effect of any type of irradiation on the proliferation or growth of cells. It is possible that irradiation during the stage of active proliferation of fibroblasts may diminish the ultimate amount of scarring, but it may be undesirable to inhibit such repair of a recently damaged cornea because of the danger of perforation.

TABLE 3

TREATMENT OF CORNEAL SCARS FOLLOWING SODIUM HYDROXIDE
BURNS WITH BETA IRRADIATION

Dosage*	No. Rabbits	Average Difference between Treated and Untreated Eyes†		Days Followed
		Corneal Opacity	Pannus	
6 gram seconds on 7th day after NaOH injection and every 2 weeks for 18 weeks.	9	+1	−2	198
6 gram seconds every 2 weeks for 12 weeks beginning 71 days after NaOH injection.	5	−8	+4	170

* Using Burnam applicator and Lucite holder, radon 6 mm. above cornea.
† Plus value = treated eye improved over untreated eye.

are sensitive to irradiation, fibrocytes in old scar tissue are not.

Relative to this problem, the corneal lesion in one eye of each of 9 rabbits which had received an intracorneal injection of 0.1 cc. of N/20 sodium hydroxide was treated with 6 gram seconds every two weeks for 18 weeks, beginning 7 days after the injection. This dose was previously found to be the maximally tolerated dose for a normal rabbit cornea. After 198 days, there was no significant difference between treated and untreated eyes (table 3).

A second experiment consisted of 5 rabbits with old sodium hydroxide scars, and the use of beta was without beneficial effect on these eyes (table 3).

CONCLUSION

Beta particles of radon represent a concentrated source of irradiation which is largely absorbed within the first 2 mm. of tissue and is therefore useful in the treatment of superficial conditions of the lid, the conjunctiva, cornea, and sclera. The effective use of beta irradiation in ophthalmology depends upon an exact knowledge of the differential between the sensitivity of normal tissues and the pathologic tissues to be destroyed.

In general, lymphoid tissues (the follicles in vernal conjunctivitis), epithelial growths (papillomas), and vascular endothelium (in corneal vascularization) form the most sensitive tissues which can be destroyed by

beta irradiation without undue injury to the normal ocular structures.

Because of the great sensitivity of the corneal epithelium and stroma cells, direct irradiation over the cornea should be used with caution.

Corneal vascularization is best obliterated by irradiation over the scleral portion of the limbus.

An ocular condition associated with great cellular destruction or pyogenic infection may respond poorly to beta irradiation.

HEREDODEGENERATION OF THE MACULA

WILLIAM L. BERKLEY, CAPT., (MC) U.S.N.
Bayshore, L. I., New York

AND

FRANK R. BUSSEY, M.D.
New York

Degenerations of the macula appear in the literature under a host of disease entities. Closer observation reveals many of these so-called entities are closely allied, if not actually identical. The confusion, which is apparent after reviewing the literature, is partially justified because of the absence of a pathologic study in the great majority of these central lesions. Thus, classifications have been based on history, funduscopic findings, and personal interpretations.

Behr,[1] in 1920, made a noteworthy attempt to clarify the situation by suggesting that a number of macular degenerations of familial and hereditary incidence be placed in one great group which he elected to call heredodegeneration of the macula. Since then there have been numerous additions to the literature of such cases. Lloyd[2] further suggested the need of "streamlining" the nomenclature of these macular lesions. The more recent texts, as Elwyn's,[3] are agreed that a condensation of the classification is preferable to the individual listing of a plethora of closely allied conditions.

This report does not purport to offer a new classification nor to suggest a modification of an older one. It is hoped simply that the presentation of another family group showing macular degeneration with some interesting associated findings (red hair and

color blindness) will prove of some value toward the final understanding of this disease. Chart 1 shows the family in question. Each case, with pertinent findings, will be discussed separately.

REPORT OF A FAMILY

GENERATION I

Case 1. A white woman, now deceased, about whom no history other than "bad eyes all her life" is known, is listed as suspected of having macular involvement.

GENERATION II

Case 1. A woman, aged 48 years, who had experienced defective vision since early childhood.

Ocular findings. Visual acuity was: O.D., 1/20 corrected to 6/20 with a +2.75D. sph. ⊃ +4.75D. cyl. ax. 15°; O.S., 1/20 corrected to 6/20 with a +3.0D. sph. ⊃ +4.5D. cyl. ax. 170°.

Funduscopic examination showed: O.D. an irregular, yellow-brown degeneration of the macula. A clearly demarcated, circular area similar in nature but of lesser degree enveloped the more central degeneration just described. The entire involved area measured 1½ disc diameters in size (fig. 1); O.S. showed a similar degeneration of lesser size but greater intensity (fig. 2).

FIGS. 1 TO 8 (BERKLEY AND BUSSEY). (FIGS. 1 AND 2) CASE 1 OF GENERATION II. O.D., THE ENTIRE INVOLVED AREA MEASURED 1⅓ DISC DIAMETERS; O.S., THE AREA OF DEGENERATION WAS SMALLER BUT OF GREATER INTENSITY. VISION: O.U., 1/20, CORRECTIBLE TO 6/20. (FIGS. 3 AND 4) CASE 1 OF GENERATION III. O.D., THE IRREGULARLY SHAPED LESION HAD A YELLOW CENTER AND A BROWNISH, PIGMENTED BORDER; VISION, 1/20, CORRECTIBLE TO 2/20. O.S. SHOWED A SIMILAR BUT MUCH OLDER LESION; VISION, 1/20, CORRECTIBLE TO 7/20. (FIGS. 5 AND 6) CASE 3 OF GENERATION III. O.D., A WELL-DEFINED, SLIGHTLY ELEVATED DISCOLORATION WAS PRESENT IN THE MACULAR REGION; VISION, 16/20, CORRECTIBLE TO 20/20. O.S., A YELLOWISH DEGENERATION INVOLVED THE ENTIRE MACULAR AREA; VISION, 1/20, NOT CORRECTIBLE. (FIGS. 7 AND 8) CASE 2 OF GENERATION IV. O.D. A CENTRAL YELLOWISH DEGENERATION HAD A CIRCUMSCRIBED AREA OF APPARENT HYPEREMIA. VISION, 16/20, CORRECTIBLE TO 20/20. O.S., THE CENTRAL LESION WAS SURROUNDED BY A MARKEDLY HYPEREMIC BORDER; VISION, 1/20, NOT CORRECTIBLE.

As a child, this patient showed a convergent squint, but no muscle imbalance was now apparent.

Case 3. A woman, aged 51 years, first noted defective vision at the age of 40 years.

Ocular findings. Visual acuity was: O.D., 1/20 not further corrected with a +1.25D. sph.; O.S., 5/20 corrected to 16/20 with a +2.75D. sph. ⊃ −2.5D. cyl. ax. 95°.

condition common to the macular area of the right eye.

Case 4. A man, aged 45 years, refused to submit to examination, stating, "I've been to eye doctors all of my life and none ever help me." This case is listed as suspected of having pathologic conditions similar to others in the family.

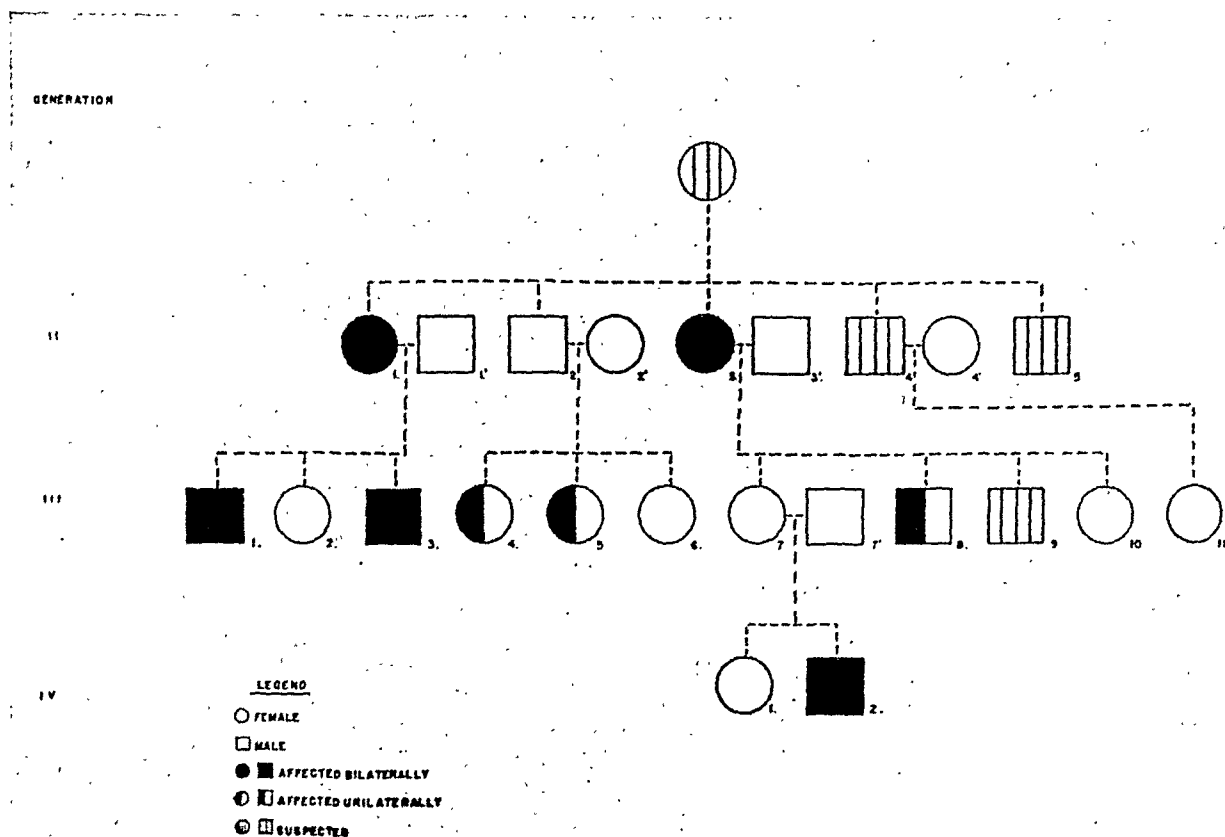
Case 5. A man, not available for examina-


Chart 1 (Berkley and Bussey). Occurrence of macular degeneration in a family group.

Funduscopic examination revealed: O.D., an irregularly shaped, rusty, "salt-and-pepper" appearing area of macular degeneration measuring about 2½ disc diameters in size. The degenerated portion was clearly demarcated from the rest of the macula (pictures not obtainable); O.S., a small, sharply demarcated, homogeneous circular lesion about one third disc diameter in size, located in the region of the macula. A rusty, irregular degeneration was noted at the upper border of the lesion. This portion of involved retina appeared to have an increased vascularity, a

tion, who is listed as suspected on the basis of a history of "bad eyes."

GENERATION III

Case 1. A young man, aged 19 years, was known to have defective vision in the left eye since the age of 12 years. One year ago he began to have defective vision in the right eye.

Ocular findings. Visual acuity was: O.D., 1/20 corrected to 2/20 with a +2.5D. sph.; O.S., 1/20 corrected to 7/20 with a +4.5D. sph.

Funduscopic examination showed: O.D.,

an extensive area of degeneration in the macular region. The lesion was irregularly shaped and was composed of a yellow center with a brownish, pigmented and poorly demarcated border that contained occasional fresh hemorrhage. The involved area measured about 2 disc diameters in size and was encompassed by a circular area of perimacular edema. (Examination recently revealed

16/20 corrected to 20/20 with a +3.0D. sph. ⊃ +1.0D. cyl. ax. 120°; O.S., 1/20 not improved with refractive correction of +4.5D. sph. ⊃ +0.75D. cyl. ax. 90°.

Funduscopic examination showed: O.D., a well-defined, circular, slightly elevated discoloration in the macular region. The lesion measured about 1½ disc diameters in size (fig. 5); O.S., presented an irregular, yel-
Fig. a (Berkley and Bussey). Visual field studies of Case 1, Generation III, showed a normal peripheral field with the presence of central scotomas.

the lesion to be quiescent with subsidence of the hemorrhage and the perimacular edema. See Figure 3.); O.S. showed a similar but much older lesion as evidenced by pigment deposits, lack of hemorrhage, edema, or other evidence of activity (fig. 4).

Field studies showed the peripheral field to be normal but the presence of central scotomas (fig. a). There was also a moderate degree of left hypertropia.

Case 2. A young woman, aged 18 years, was free of any apparent macular involvement. She is listed merely to note the presence of a marked weakness of the left superior rectus with resultant right hypertropia.

Case 3. A boy, aged 14 years, noted defective vision in the left eye at the age of 12 years. There were no complaints referable to the right eye save the need for the refractive correction.

Ocular findings. Visual acuity was: O.D.,

lowish degeneration of the entire macular area (fig. 6).

Case 4. A young woman, aged 25 years, has had no complaints referable to the eyes.

Ocular findings. Visual acuity was: O.D., 16/20 corrected to 20/20 with a +1.5D. sph.; O.S., 20/20.

Funduscopic examination showed: O.D., the macula had a definite moth-eaten appearance typical of an early stage of degeneration; O.S., normal.

Case 5. A woman, aged 23 years, complained of "weakness of the right eye."

Ocular findings. Visual acuity was: O.D., 16/20, not further correctible; O.S., 20/20.

Funduscopic examination presented: O.D., a rusty appearance of the macula with a small amount of punctate stippling which is considered characteristic of an early stage of macular degeneration; O.S., normal.

Case 8. A man, aged 28 years, had no visual complaints.

Ocular findings. Visual acuity was: O.D., 20/20; O.S., 20/20.

Funduscopic examination showed: O.D., a faint homogeneous and circular area of apparent degeneration was present in the macular region; O.S., normal.

Case 9. A man, aged 26 years, was not available for study. Listed as suspected on basis of history of longstanding "bad eyes."

GENERATION IV

Case 2. A boy, aged 8 years, had a history of poor vision in the left eye since infancy.

Ocular findings. Visual acuity was: O.D., 16/20 corrected to 20/20 with a +2.0D. sph.; O.S., 1/20 not further corrected with a +4.5D. sph., the retinoscopic finding.

Funduscopic examination showed: O.D., the macular area had a central yellowish degeneration with a circumscribed area of apparent hyperemia more than 1 disc diameter in size (fig. 7); O.S., the macula had a distinct circular degenerative area about 1½ disc diameters in size. The central lesion was surrounded by a markedly hyperemic border (fig. 8). Examination six months later showed development of some pigmentation in both eyes.

An esotropia was present in early childhood, but the condition had been slightly improved by his refractive correction.

DISCUSSION

Genetically, this family revealed "a condition of dominant transfer with imperfect penetrance" according to a personal communication from Dr. T. H. Dobzhansky.[4] He further stated that "if Case 2* in Generation II and Case 7* in Generation III had evidence of the disease, the conditions for perfect dominance would have been satisfied." Rechecks were done of these two cases but no evidence could be found of any pathologic condition.

According to the pattern of onset, which in this study showed a wide variation (from

infancy to adulthood), it is still possible that these two cases may develop evidence of the disease. This is especially true of the individual in Case 7 of Generation III who is still relatively young.

PATHOGENESIS

The literature is sparse and nonrevealing as to a definite pathology or etiology of heredodegeneration of the macula. Lues, tuberculosis, and other systemic diseases have been designated as causative factors. Ferrié[5] recently presented four additional cases of degenerative macular disease associated with definite evidence of tuberculosis. However, it would appear that this finding was merely coincidental.

There was no evidence to suggest consanguinity, lues, tuberculosis, or central nervous-system disorder in any of the cases we have presented. The optic nerve in most of the cases showed a definite temporal pallor. This observation has been noted in connection with degenerative macular disease by others (Crawford[6]).

GENERALITIES DRAWN FROM THIS REPORT

The disease is interesting from the standpoint of the ophthalmologist and the geneticist, and should be borne in mind in studies of macular abnormalities. Much assistance to the patient may be offered in the form of correction of refractive error, assurance that blindness will not ensue, and elimination of unnecessary empirical approaches to therapy.

SUMMARY

1. A family group showing positive occurrence of macular degeneration in 8 cases and possible occurrence in 3 additional cases is presented.

2. Color illustrations representative of typical lesions are shown.

3. The cases are reviewed individually and certain associated findings are noted. These include similar funduscopic appearance, hyperopia with and without astigmat-

---

* Not reported herein.

tism, muscle imbalances, central scotomas, temporal pallor of the nervehead, red hair, and color blindness.

4. Onset (clinical) seemed relative to periods of physiologic stress and cases are listed as occurring at infancy, puberty, adolescence, early adulthood, and presenile period.

5. The hereditary transfer in this family was "dominant with imperfect penetrance."

CORRELATION OF THE CEREBROVASCULAR RESISTANCE AND THE GRADE OF HYPERTENSIVE RETINAL FINDINGS*

IRVING H. LEOPOLD, M.D., SEYMOUR S. KETY, M.D., WILLIAM A. JEFFERS, M.D., JOSEPH H. HAFKENSCHIEL, M.D., AND HENRY A. SHENKIN, M.D.
Philadelphia, Pennsylvania

Within recent years there has been an increasing interest in the hypertensive patient. Many hypertensive patients are being studied with the hope that they may improve following a thoracolumbar sympathectomy. It is not always a simple matter to determine which patients may be expected to benefit from the operative procedure. Various studies are employed in order to aid in the proper patient selection. Studies such as electrocardiogram, orthodiagram, influence of sodium-amytal narcosis on blood pressure, effect of a differential spinal, cold-pressor test, tests of renal function, and eyeground evaluation are all made. At present hypertensive patients are being studied at the Hospital of the University of Pennsylvania by a group of physicians who hope to correlate their data and, perhaps, eventually to arrive at some firm basis on which to select patients for surgical treatment. During this study the eyegrounds have been examined and classified according to the retinal vascular findings.

The classifications of eyeground findings as suggested by Wagener, Keith, and Kernohan,[2] and others, were deduced primarily on the duration of life of the patient and the severity of the hypertension. It seems desirable, if possible, to correlate these grades of hypertensive retinal changes with other physiologic factors. Such an opportunity presented itself among the hypertensive patients following measurement of their cerebral blood flow. Other data in this same study are reported elsewhere.[1] In this study it has

been shown that the cerebral blood flows are normal in the hypertensive patient.

From the cerebral blood flow the cerebrovascular resistance can be calculated.* The cerebrovascular resistance may be recorded as the pressure reuired to drive 1 cc. of blood through 100 gm. of brain tissue per minute.

similar alteration in the resistance of the cerebral vessels?

Twenty-one hypertensive patients and three nonhypertensive patients were studied. All the eyegrounds were graded according to the method of Wagener, Keith, and Kernohan.[2] It is admitted that it is not always pos-

The cerebrovascular resistance can be compared with the grade of retinal vascular change. At the same time another important factor can be evaluated. Since controversy exists as to whether retinal vascular changes reflect the state of the cerebral vessels, our observations appear to offer a new approach. Does increased retinal vascular resistance, as judged by narrowed vessels, sclerotic vessels, hemorrhages, and exudates, suggest a

sible to decide which type of sclerosis exists or to differentiate sclerosis and spasm, and that many ophthalmologists disagree in their interpretation of actual retinal findings. This classification, however, has been accepted as a helpful guide by many ophthalmologists. The fundi were graded by this method without any previous knowledge of the cerebrovascular resistance.

The cerebral blood flow was measured by the nitrous-oxide method of Kety and Schmidt.[3,4] This employs the use of a gas mixture consisting of 15-percent N_2O, 64-percent N_2, and 21-percent O_2. Specimens

---

* The cerebral blood flow (cc. of blood passing through 100 gm. of brain tissue per minute) divided into the mean blood pressure equals the cerebrovascular resistance.
Graph 1 (Leopold, *et al.*). Cerebrovascular resistance in patients with various grades of hypertensive retinal changes.

for analysis were withdrawn simultaneously from the jugular bulb and femoral artery. Mean arterial blood pressure was obtained by means of a damped mercury manometer attached to a needle in the femoral artery. Cerebral metabolic rate in terms of cerebral oxygen consumption and cerebrovascular resistance were calculated as previously described.[3] Blood gas analyses were made in the Van Slyke-Neill manometric apparatus.[5] Potentiometric measurement of blood pH was made anaerobically at 37°C. by means of a glass electrode. Values for blood carbondioxide tension were calculated by means of the nomograms presented by Peters and Van Slyke.[5]

The results of the ophthalmoscopic gradings of the cerebral blood flow and the cerebrovascular resistance for each patient are listed in Table 1. It can be seen from a study of Table 1 and of Graph 1* that there is a tendency for the grade of hypertensive ret-inal change to increase as the cerebrovascular resistance increases. The statistical method†

* In an attempt to spread out the largest groups for graphing purposes, Wagener's Grade II was subdivided into IIa and IIb on the basis of the severity of spastic or sclerotic change. Grade III was also broken arbitrarily into a and b. Less than 10 hemorrhages and exudates in both eyes placed the eye in Grade IIIa.

† Spearman's formula was employed for this calculation

$$rho = 1 - \frac{6\Sigma(D^2)}{N(N^2-1)}$$

Where rho is the measure of correlation
  D is the difference between the two ranks given for each individual
  N equals the number of individuals
The coefficient of correlation (r) can be found by the formula
  r = 2 sin

$$\frac{(\Pi\ rho)}{6}$$

In the case of ties of rank, the bracket method was employed. In this method all ties are assigned the same rank, but the next higher individual is given

of measuring correlation from ranks showed that a significant correlation existed.

From these results it is evident that when the retinal vessels showed signs of hypertension, the cerebrovascular resistance was elevated. Although there is a definite tendency for the grade of retinopathy to increase as the cerebrovascular resistance increases and this has been shown to be statistically significant, it is also true that overlapping occurs. A patient with retinal changes of a Grade I degree may have an increased cerebrovascular resistance that might also occur in a patient with a Grade II or III type of fundus. Although there is a direct relationship between the retinal and cerebral circulation, it is also evident that one cannot accurately predict from an ophthalmoscopic study of the retina and retinal vessels in a single individual the exact extent to which the cerebrovascular resistance has been elevated.

It is conceivable that, if other types of sclerosis, such as localized and diffuse

the rank that would have been assigned if the ties had received successive ranks.

r was found to be 0.67 and p was less than 0.001, indicating a high degree of statistical significance.

atherosclerosis, could be more thoroughly separated from hypertensive retinal vessel changes, a different correlation might exist for, in all probability, these factors also influence cerebral blood flow and cerebrovascular resistance.

SUMMARY

1. The cerebrovascular resistance was calculated from measurements of the mean blood pressure and of the cerebral blood flow, and the eyegrounds were evaluated in 21 hypertensive and 3 nonhypertensive individuals.

2. A statistically significant correlation was found to exist between the grade of retinal hypertensive change and the cerebrovascular resistance. The relationship was a direct one in that as cerebrovascular resistance increased, the grade of retinopathy also tended to increase.

3. It is evident that the retinal findings do reflect with some accuracy the state of the cerebral circulation but the degree of accuracy is not marked in that one cannot predict from the ophthalmoscopic findings the exact extent to which the cerebrovascular resistance has been elevated.

ESSENTIAL PROGRESSIVE ATROPHY OF IRIS*

Louis W. Chang,† M.D.
Nanking, China

AND

Gaylord W. Ojers, M.D.
Philadelphia, Pennsylvania

The purpose of this article is to report three cases of essential atrophy of the iris, two of which showed peripheral anterior synechias in the region of developing iris atrophy. Such a relationship seen in a relatively early development of the disease suggests that the atrophy may be secondary to traction upon the delicate iris tissue. The third case was complicated by a severe secondary glaucoma which suggests that peripheral anterior synechias would have been seen if either a slitlamp or gonioscope had been available for the examination.

Essential iris atrophy is an uncommon disease, occurring predominantly in young women, in which the tissue of the iris disappears slowly and without symptoms. These patients usually consult an ophthalmologist because of an eccentric pupil or symptoms of secondary glaucoma which commonly accompanies the condition. Fortunately, the disease is rarely bilateral.

The atrophy usually begins in such a way that the pupil becomes eccentric and eventually may be pulled to the base of the iris. During this time the pigment epithelium often becomes everted. Opposite the displacement of the pupil, small holes may appear either superficially in the anterior layers or perforating the entire thickness of the stroma. Later these enlarge and may even coalesce. Less frequently the disease begins in another way. Small depigmented areas are noted first. These gradually extend in size and fuse to involve the different layers or entire thickness of the iris.

Although this disease is rare, reports of cases have been appearing in the literature with not too irregular frequency since 1886.[1] Because gonioscopic examination has been done in only five cases (McKeown,[2] Post,[3] Scharf,[4] and Sugar[5]) such an examination of our first patient is of interest.

CASE REPORTS

CASE 1

History. Mrs. A. R., aged 37 years, white, was first seen on April 29, 1947, through the courtesy of Dr. Francis Heed Adler. She had noted that the pupil of the right eye was irregular. Vision was 6/7.5 in each eye uncorrected.

External examination was normal except for the eccentric right pupil which was displaced slightly downward and considerably outward. Both pupils reacted promptly, although the lower outer third of the right pupil seemed quite immobile. Two pigmented areas could be seen at midportion on the iris of the right eye (fig. 1).

Ophthalmoscopy. On the temporal side of the right undilated pupil a space between the iris and the lens exposed the anterior portion of the ciliary processes. The iris appeared to be pulled forward by some cicatricial process in the angle. No mass was seen.

Slitlamp examination revealed that the right iris angle had been obliterated from approximately the 7- to the 8:30-o'clock positions; the iris appeared to be drawn in this direction with resultant pupil displacement. Neovascularization was seen at the point of adherence. No evidence of a perforating injury could be found. The dark areas on the iris previously mentioned represented areas
Fig. 1 (Chang and Ojers). External appearance of right eye as seen through a magnifying glass. The deviation of the pupil and holes of iris are clearly shown. (Case 1.)

and the anterior portion of the ciliary body were visible. No mass could be visualized pushing the iris forward (fig. 2).

Tension was 25 mm. Hg (Schiøtz), O.U., on August 25, 1947. No increase of tension was found on successive visits. Peripheral synechias were more extensive on September 27, 1947.

CASE 2

History. The following case of F. W., a 23-year-old white soldier, was contributed by Dr. Harold G. Scheie. The left eye showed a marked iris atrophy with displacement of the pupil temporally.

Gonioscopic examination could not be done but slitlamp examination demonstrated extensive peripheral anterior synechias in the direction of atrophy. The pupil was pulled away from the lens, permitting visibility of the ciliary process between the iris and the lens, much as seen in Case 1. The rest of the ocular examination, including tension, was normal.

CASE 3

History. Miss H. N. C., Chinese, aged 15 years, was admitted to the Central Hospital, Nanking, April 17, 1947, because of progressive visual loss since childhood, greatly accentuated in the last month.

Visual acuity (with and without correction) was: O.D., hand movements at 30 cm.;

of atrophy in the stroma with exposure of the pigment layer. In being displaced, the iris had been pulled so far forward that it was no longer in contact with the lens from the 4- to the 10:30-o'clock positions.

Gonioscopy of the same eye showed extensive peripheral anterior synechias from the 7- to 8:30-o'clock position. Further synechias were found, both at the site of the stromal atrophy (5 o'clock) and at 10 o'clock. The iris at the areas of the larger synechias was pulled forward in such a manner that the underside of its posterior layer

Fig. 2 (Chang and Ojers). Angle chamber of right eye viewed with gonioscope. Note the peripheral anterior synechias pulling the pupillary border toward the periphery and exposing the ciliary processes. (Case 1.)
O.S., finger counting at 30 cm. Examination of lids and adnexa of both eyes was negative.

O.D.: The cornea was normal. The anterior chamber was shallow. A large colobomatous iris defect extending to the ciliary body was seen from the 5- to the 9-o'clock positions. Just at the apex of the coloboma was a small elongated hole which contracted sluggishly to light. There were no visible synechias nor ectropion of the pigment margin. Although normal crypts could be seen in the brown iris, there was no distinction between ciliary and pupillary zones (fig. 3, O.D.).

The lens was clear, and its equatorial margin could be seen through the coloboma. Fine white shreds, presumably exfoliating lens capsule, and tiny pigment deposits were present over the anterior surface. The vitreous was clear.

The eye grounds were seen with a −20D. lens. The pale disc was deeply cupped on the temporal side, and an area of choroidal atrophy extended from this side to the normal appearing macular region. Coursing over the tessellated retina were normal retinal vessels.

O.S.: The iris was similar in structure and color; however, the defect was so huge that it occupied about two thirds of the chamber. The defect was kidney-shaped and extended to the temporal limbus from the 1- to 5-o'clock positions. From the 2- to 3:30-o'clock positions a small iris nubbin was seen attached to the ciliary body. There was a small hole at 9 o'clock which extended to the limbal region. As pilocarpine caused this area to constrict, it was assumed to be the remainder of the pupillary aperture. Fine pigment deposits and white shreds were scattered over the surface of the transparent lens. The vitreous was clear (fig. 3, O.S.).

The fundus was seen with a −25D. lens and appeared essentially the same as described for the other eye, except the cupping of the disc was not so pronounced.

Tension was: O.U., 54 mm. Hg (Schiøtz). Visual fields could not be taken because of poor vision. Tension was brought down to 17 mm. Hg, O.U., by the use of pilocarpine nitrate (2 percent) every two hours.

Fig. 3 (Chang and Ojers). External appearance of right and left eyes examined with a loupe. Note the colobomatous defects in both eyes. An attempt has been made to show the white shreds and pigment deposits on the anterior capsules of both eyes. (Case 3.)

The ultimate outcome, however, is unknown, for the patient was observed for only one week before she returned to the interior of China.

DISCUSSION

In a review of the literature of essential iris atrophy, Henderson and Benedict[6] divided the reported cases into three groups. Group I consisted of those cases with no demonstrable cause for the atrophy and uncomplicated by glaucoma. Group II was the same as the above except glaucoma was present when the case was first seen. Group III included all those cases in which the atrophy was suspected to have been secondary to some etiologic agent. Our first and second cases belong to Group I. But our third case is puzzling and may well belong to Group III.

While the appearance of the lens capsule in this last case was that of exfoliation (by loupe examination), the earliest case of glaucoma capsulare previously reported has been in a 41-year-old man (Gradle and Sugar[7]). It is possible, of course, that the process responsible for the atrophy was also detrimental to the capsule. Pigment deposits on the lens capsule may well represent a low-grade inflammatory process. On the other hand, pigment deposits are seen in some cases of primary glaucoma. It is of further interest that this case is bilateral. Only six bilateral cases have been reported (Yao,[8] Fine and Barkan,[9] McKeown,[10] Rosenberg,[11] and Czukrasz[12]) and doubt has been expressed as to the diagnosis in the case reported by Fine and Barkan (Henderson and Benedict[6]).
As so often happens when proof is difficult, many theories as to etiology have been presented. Larson[13] feels the condition is a congenital anomaly. Feingold[14] also suggests it is of congenital origin but places the disturbance in the blood vessels of the smaller iris circle. De Schweinitz[15] suggests some autotoxin or possibly abiotrophy.

A cytolytic process representing a perversion of a normal embryonic function has been postulated by Kricker[16] and Jeancon.[17] Von Grosz[18] favors a neurogenic factor. Vascular change is mentioned by Zentmayer[19] and Lane.[20]

Mechanistic theories start with the thought that the atrophy is secondary to the stretching of the iris (Rochat and Mulder[21]). This idea is carried further by Waite[22] who suggests an interference with the blood supply caused by the narrowing or occlusion of the radial vessels as a result of the pull on the iris tissues. The fact that our first two cases were seen to show atrophy in the line of stress caused by the peripheral synechias would support these mechanistic theories.

Evidence as to the causes of glaucoma characteristically complicating the later stages of essential iris atrophy has been well reviewed by Sugar.[5] The constant findings of peripheral anterior synechias, both by gonioscopic examination and microscopic study of enucleated eyes, appear to support Rochat's and Mulder's hypothesis[21] that the cementing together of the iris and cornea results in the slow obliteration of the chamber angle with a consequent rise in tension.

Peripheral anterior synechias were found in our first two cases, but they were not complicated by glaucoma. This need not be surprising. Only as these cases progress to the point where synechias become sufficiently extensive to embarrass the drainage system of the angle will the intraocular pressure rise. It has been estimated that as little as 70 to 90 degrees of an arc of normal angle is sufficient to allow a normal tension in narrow-angle glaucoma with peripheral anterior synechias (Kronfeld[23]). Although no synechias were seen in the case of the Chinese patient, who did have a marked rise in ocular tension, it seems almost certain that peripheral anterior synechias would have been revealed by a slitlamp or gonioscopic examination.

CONCLUSION

1. Three cases of essential iris atrophy are presented.
2. Peripheral anterior synechias were

demonstrated by either slitlamp microscopy or gonioscopy (or both) in Cases 1 and 2. It is felt that anterior synechias were probably present in Case 3 because of the presence of secondary glaucoma.

3. The peripheral anterior synechias in the first two cases were so situated that the atrophy of the iris could well have been due to the mechanical displacement and subsequent stress on the iris.

OPHTHALMIC MINIATURE

The more attentively we observe the phenomena of disease, and consider the effects of remedies, the more we shall be led to adopt simplicity of treatment, and the less confidence shall we place in complicated plans, or great diversity of remedial means.—Sir William Lawrence, *A Treatise on the Diseases of the Eye,* 1833.

INVESTIGATION OF THE BLOOD-AQUEOUS BARRIER IN THE NEWBORN*

I. To Ascorbic Acid

V. Everett Kinsey, Ph.D., and Blanche Jackson, Ph.D.
Boston, Massachusetts

The objective of these studies was to investigate aqueous-humor dynamics in the newborn. Information on this subject may be essential for an understanding of the significance and possible relation of several manifestations of eye pathology observed in retrolental fibroplasia. Specific structural abnormalities which may be related include shallow anterior chamber, thin and elongated ciliary processes, and presence of a vascular system behind the lens. Abnormally low ascorbic acid concentration of the aqueous humor in eyes with retrolental fibroplasia[1] (approximately that found in the blood) indicates that the composition of the aqueous humor differs from that characteristic of the normal, adult human being.

In preliminary studies,[2] the level of ascorbic acid in the aqueous humor of the rabbit at birth was shown to be the same as in the plasma. After the 9th day, a progressive increase occurs until the normal adult level (25 to 30 mg. percent) is reached approximately 27 days after birth. This was thought to indicate that secretion by the ciliary body does not start until the animals are approximately 9 days old.

Further consideration of the implications of these results suggested that the situation is probably more complex, and that additional investigations were necessary for a clearer understanding of the changes undergone in the dynamics of intraocular fluids in the developing eye.

The immediate objects of the present paper were, first, to determine whether the changes in concentration of ascorbic acid in the aqueous humor of other species vary with age in a manner similar to that in the rabbit, and secondly, to consider other mechanisms which might account for the experimental findings.

Methods

Samples of aqueous humor were obtained from rhesus monkeys varying in age from newborn to 4 years.[†] In all instances, the aqueous humor was transferred directly from the microsyringe used for collection of the sample into tubes containing 0.2 ml. of 5-percent metaphosphoric acid. After centrifuging, analysis for ascorbic acid was made by titration with 80 mg. percent 2,6 dichlorophenolindophenol, again utilizing micro techniques.

The specimens of aqueous humor from infants were obtained as soon after death as possible; the time elapsing between death and collection of the sample varied from 45 minutes to 48 hours. Since all of the samples collected 12 hours or more after death fell within the normal adult range, it is assumed that little, if any, destruction of the vitamin occurs *in situ* in the eyes of infants who were placed in cold rooms prior to autopsy. In addition to the samples of aqueous humor obtained after death, several specimens were obtained from eyes enucleated from living individuals.

Results

The ascorbic-acid concentrations of aqueous humor obtained from monkeys of var-

† The monkeys (Macaca mulatta) for this study were made available through the courtesy of Dr. G. van Wagenen of the Department of Obstetrics and Gynecology, Yale University School of Medicine. The colony is maintained through funds donated by the Nutrition Foundation, Inc., New York, New York.

ious ages are given in Figure 1. The concentration from the day of birth until shortly after the first month of life is 2 to 3 mg. percent, or approximately the same level as that in the blood. Following this, the concentration increases until the adult level of 16 to 19 mg. percent is reached about the 6th month.

The ascorbic-acid content of aqueous humor obtained from human beings of different ages is plotted in Figure 2. While the data are few, they seem to indicate that (1)

DISCUSSION

The results of all three species studied—the rabbit, monkey, and man—indicate that the aqueous humor dynamics during the developmental stages of the eye differ markedly from those of the adult with respect to ascorbic acid at least. It seems worthwhile to consider the possible factors which might account for this variation.

As a basis for understanding alterations in the mechanism of aqueous-humor dynamics, particularly as they relate to the transfer of
Fig. 1 (Kinsey and Jackson). This graph shows the concentrations of ascorbic acid in the aqueous humor of monkeys at various ages.

the concentration increases during the last 2 months of fetal life, and (2) individual variation of concentration of ascorbic acid in the aqueous humor at birth is less than that encountered later in life. Because of the variation in the ascorbic-acid content of the adult aqueous humor, the normal level cannot be well defined. However, the ascorbic-acid concentration of the aqueous humor of the full-term infant falls within the range of that of the normal adult having an adequate ascorbic-acid intake.

ascorbic acid, some of the factors thought to influence the accumulation of this acid in the adult eye will be described.

Ascorbic acid is believed to act as a mediator in the oxidation-reduction reactions thought to be associated with the transfer of electrolytes from the blood to the posterior chamber.[3] In the chain of energy-yielding reactions, the vitamin apparently is oxidized to the dehydro form, in which state it is presumed to diffuse into the aqueous humor to be reduced by the sulfhydryl

groups in the lens. To account for the relatively high concentration in the aqueous humor compared with that in the blood, it is further assumed that the blood-aqueous barrier is less permeable to the diffusion of ascorbic acid than to dehydroascorbic acid. Steady-state conditions are further depend-

discussed heretofore[2] to account for differences in concentration of ascorbic acid in the newborn and that reached subsequently was alteration of the rate of secretion. Final evaluation of this factor should properly be delayed until evidence is obtained from direct studies of the ciliary body at different
Fig. 2 (Kinsey and Jackson). This graph shows the concentrations of ascorbic acid in the aqueous humor of human beings at various ages.

ent upon the rate of loss of ascorbic acid from the anterior chamber by the flow or leakage process described elsewhere.[4]

Thus, the eventual concentration of ascorbic acid in the aqueous humor may be dependent on (1) the rate of secretion and/or diffusion of dehydroascorbic acid into the aqueous humor, (2) the capacity of the lens to reduce dehydroascorbic acid to ascorbic acid, (3) the relative permeabilities of the blood-aqueous barriers to the oxidized and reduced forms, and (4) the rate of outflow.

Of the factors listed above, the only one

ages, using the techniques devised by Friedenwald and Stiehler for selective transfer of acid and basic dyes by ciliary epithelium and stroma, distribution of the enzyme systems associated with the secretion, and so forth.[5]

Regarding the capacity of the lens at various ages to reduce the dehydroascorbic acid to ascorbic acid, analysis of a 1-day-old rabbit lens showed the glutathione concentration to be 169 mg. percent. This concentration is approximately half that found in the normal adult and, assuming that its rate of re-

newal is at least as high as that in the adult lens, it would be more than sufficient to reduce the small quantity of dehydroascorbic acid transferred into the aqueous humor of the eyes in the animals at this age. It may be significant, too, that the ascorbic-acid concentration of the lens is already at the normal adult level (11 mg. percent).

The third factor already mentioned which influences the concentration of ascorbic acid in the aqueous humor is the relative permeability of the blood-aqueous barrier to the diffusion of ascorbic and dehydroascorbic acids. In the adult, the chief sites of the blood-aqueous barrier are the iris and ciliary body, but in the eye of the newborn the tunica vasculosa lentis network of the hyaloid system must also be considered as part of the blood-aqueous barrier.

It is pertinent to follow the condition of the hyaloid system during the period in which the concentration of ascorbic acid in the aqueous humor is increasing to the level characteristic of the adult eye. The rabbit eye at birth is richly supplied by the hyaloid system. At this time, the ascorbic-acid level in the aqueous humor is the same as that found in the blood. By the 9th or 10th day after birth, although the system has regressed significantly, blood is still circulating through it, and the ascorbic acid concentration of the aqueous humor is still at blood level. By the 14th or 15th day, however, the vessels have disappeared completely, and concentration of ascorbic acid in the aqueous humor is increasing but has not yet reached the level found in the adult eye.

Information now available concerning the time of regression of the hyaloid system in the rhesus monkey is incomplete, being limited to observations made on the eye of a single animal obtained on the day of birth. In this eye, the lesser branches of the hyaloid system were already partially closed. It is possible that the hyaloid vessels of the monkey may continue to function to some degree for several weeks after birth. If this is true, the age at which the hyaloid system regresses in the monkey also seems to coincide with onset of increase in concentration of ascorbic acid in the aqueous humor.

In human beings, the main trunk of the hyaloid artery shrinks considerably during the 7th month of fetal life, and the pupillary membrane begins to atrophy. By the end of the 9th month, the pupillary membrane and the hyaloid artery have practically disappeared.[6] Analysis of the sample of aqueous humor obtained from the youngest human fetus (6¾ months) suggests that at this stage the ascorbic-acid concentration has already begun to rise. Thus, in man also, the time of regression of the hyaloid system parallels the initial increase in concentration of ascorbic acid in the aqueous humor.

The analyses from all the species therefore indicate a reasonably close time relationship between the breakdown of the hyaloid system and the initial rise of ascorbic acid in the aqueous humor. The final (adult) level of ascorbic acid does not, however, coincide with the complete regression of the hyaloid system in all the species. In the rabbit, the delay amounts to about 12 days; in the monkey, possibly as long as 4 to 5 months; and in man, the correlation appears to be relatively closer—of the order of 2 weeks. Direct experimental evidence has been obtained that ascorbic acid exchanges between blood and aqueous humor in the rabbit during the 12-day period following closure of the hyaloid system more freely than it does in the adult eye.[7]

The possible effect produced by variations in the rate of outflow on the concentration of ascorbic acid in the young and adult animal remains to be discussed. Kinsey and Grant[4] have considered the influence of this factor on the distribution of solutes between the aqueous humor and the blood under steady-state conditions and have expressed the relationship mathematically.

If it is assumed that in the adult rabbit eye the major loss of ascorbic acid is by flow, and evidence for this has been obtained,[7] and also assumed that the relative

rate of secretion of ascorbic acid into the posterior chamber is the same for young and adult rabbits, then it follows that the rate of outflow would have to change tenfold to account for the tenfold change in ratio of concentration in the aqueous humor to concentration in the blood, that is, from 20 found in the adult rabbit to 2 as found in rabbits 8 to 10 days old.

While changes in permeability factors of this order of magnitude are frequently encountered, it seems unlikely that any factors known to influence the rate of flow, such as intraocular pressure or changes in width of the angle, would vary to such a degree.

In conclusion, it seems that the observed changes in concentration of ascorbic acid could be accounted for almost entirely by changes in the permeability of the blood-aqueous barrier undergone during this period of development. From the fact that the ascorbic-acid levels in the aqueous humor and blood were indistinguishable during the period in the life of all the species when there is a discrete hyaloid system present, it might be inferred that the presence of this vascular system alone could account for the experimental findings. The subsequent delay in the rise of ascorbic-acid concentration of the aqueous humor suggests that the barrier properties of the iris and/or ciliary body are also changing during the time interval under consideration. It is possible also that simultaneous variations may occur in the secretory rate and perhaps in rate of leakage.

SUMMARY

The ascorbic-acid concentration of aqueous humor has been determined in young monkeys (Macaca mulatta) and in infants of various ages. In the monkey, as was shown previously for the rabbit, the concentration increases from that in the blood to that characteristic of the adult eye during the period 6 weeks to 6 months after birth. In the human being, a similar rise occurs between the 6th and 9th fetal months.

The following factors were discussed to account for the experimental findings:

1. Increased rate of secretion.
2. Capacity of lens to reduce dehydroascorbic acid to ascorbic acid.
3. Variations in properties of blood-aqueous barrier.
4. Alterations of outflow.

The observed changes in concentration of ascorbic acid seem to correlate best with regression of the hyaloid system and subsequent changes in the permeability of the iris-ciliary body barrier between the blood and the aqueous humor.

TRAUMA TO THE HEAD WITH PARTICULAR REFERENCE TO THE OCULAR SIGNS*

PART II.† INJURIES INVOLVING THE HEMISPHERES AND BRAIN STEM; MISCELLANEOUS CONDITIONS; DIAGNOSTIC PRINCIPLES; TREATMENT

ARTHUR B. KING, M.D., AND FRANK B. WALSH, M.D.

Baltimore, Maryland

3. HEMISPHERE AND BRAIN-STEM LESIONS

HEMISPHERE LESIONS

In addition to the temporary neurologic signs produced by intracranial collections of blood, a variety of neurologic defects may remain following injury to the hemispheres and brain stem.

Monoplegia, apraxia, hemianopia, aphasia (sensory and motor), and cortical blindness may follow cortical lacerations produced by indriven bone fragments and foreign bodies. Injury to a major vessel, especially the middle cerebral or one of its larger branches, results in hemiplegia. Signs produced by injuries tend to be pronounced at first and to show great improvement with passage of time.

Lacerations at the base of the frontal and temporal lobes are a common occurrence and produce extensive subpial and subarachnoid hemorrhages. Not infrequently large parts of these lobes are reduced to a hemorrhagic necrotic pulp. While signs of high intracranial pressure are prominent, few localizing symptoms are seen. Convulsions may be severe.

Lowered blood pressure due to hemorrhage or shock may predispose to thrombosis. Often thromboses develop while the patient is conscious. The occlusions may be arterial or venous. Depending upon the extent of the thromboses various symptoms ensue. Coma, asphyxia, and hemiplegia are most often seen. Dural sinuses may become thrombosed and produce tremendous increase in the intracranial pressure. Cerebral paraplegias (superior longitudinal sinus) and proptosis (cavernous sinus) are occasionally seen.

Ocular Signs of Hemisphere Lesions

Apart from conjugate deviations of the eyes which are associated with epileptiform seizures (occurring in a small percentage of cases of head trauma) pronounced deviations of the eyes occur infrequently as a result of injury to the head.

Frontal lobe lesions. It might be anticipated that injury to the frontal lobe would often produce pronounced deviation of the eyes (to the side of a destructive lesion and away from an irritative lesion). Undoubtedly such deviations occur in some instances but they do so rarely and we have not observed them. It is to be assumed that the anterior oculogyric pathways are interrupted infrequently. This applies also to the posterior oculogyric pathways if pronounced conjugate deviation is an accurate criterion.

Prefrontal lobotomy affords an interesting example of frontal lobe trauma. In such cases we have not observed pronounced deviation of the eyes in any instance. Occasionally there has been inabilty to move the eyes on request for a short time following operation but this has been inconstant and seemed to be due to lack of attention.

Pseudohemianopia develops in some instances of excision of a frontal lobe. In some such cases there has been a transitory deviation of the eyes to the side of the removal; also there has been what appeared to be defective perception in the contralateral visual field. This is not a true hemi-

anopia and probably represents only lack of attention.

Lesions of the parietal lobe. Lesions involving the parietal lobe produce sensory involvements predominantly. Among these are sensory fits, loss of postural sensibility, and loss of tactile discrimination in the areas of the body on the opposite side corresponding to the cortical representation.

Stimulation of the angular gyrus produces conjugate deviation of the eyes to the side opposite the stimulation just as in the instance of stimulation to Area 8 of the frontal lobe. Also there may be deviation of the eyes to the side of a destructive lesion. Such ocular deviations are neither as pronounced nor as constant in their occurrence as when the frontal lobe is involved. The ocular deviations associated with lesions involving this secondary center are due to interference with the optic fixation reflexes; that is, they influence the posterior oculogyric pathway.

The angular gyrus is an area which is considered of great importance. It is thought of as a center for word-memory. Lesions situated in this general region produced word blindness (alexia). There are various types and degrees of word blindness. In its purest variety it is fairly well agreed that the angular gyrus region usually is affected.

Henschen's[31] extensive work on this shows, however, that pure word blindness may be associated with lesions situated elsewhere in the cortex. With word blindness there may be an associated hemianopia, and it is recalled that involvement within the parietal lobe may directly involve the optic radiation. It has been suggested that a lesion in the superior portion of the cuneus may produce alexia and that it may originate in involvement of the occipital lobe or as the result of a lesion in the corpus callosum.

Spatial agnosia has resulted from bilateral involvement of the angular gyrus as described by Holmes[32] in traumatic cases. His patients exhibited errors in judgment as regards distances, walking into obstacles in the path, inability to count coins, accommodation retardation, and loss of the blink reflex as well as loss of stereoscopic vision.

Riddoch[33] described such cases when the phenomena observed in Holmes's cases were present only in the homonymous half-fields. Trescher and Ford[34] described a case in which there was loss of object vision in the homonymous half-fields as a result of splitting of the corpus callosum; also in their case there was loss of topographic memory which characterized some of Holmes's cases.

Brain[35] has described such anomalies of vision as are mentioned above in a person whose fields were normal. Defects in integration of visual perceptions at a higher level than the primary projection areas arise from lesions involving the parietal, occipital, temporal, and even the frontal lobes. Our present knowledge regarding the lesions responsible for these abnormalities is incomplete. They have little significance in topical diagnosis other than they arise as a result of injuries in the region of the angular gyrus and posterior to it.

Lesions of the temporal lobe. In this lobe, visual-field defects are the outstanding characteristic. Homonymous sector-shaped defects indicate interruption of the lower portion of the optic radiation where the fibers are fanned out in the forward portion of the temporal lobe. Sector defects and complete homonymous hemianopia with or without sparing of the macula originate in interruptions of the optic radiation at the level of the temporal lobe. In some instances the field defects are not completely congruous, as has been pointed out by Harrington.[36] The suggestion that incongruity of the defects is due to pressure upon or involvement of the underlying optic tract has been mentioned by Traquair[37] in the instance of tumorous involvement.

Occipital lobe lesions. The cortical localization concept of Holmes and Lister[38] was established during World War I on the basis of a study of war wounds, and during World War II has been verified. Other evidence

which supports this localization concept has been obtained from patients who have been subjected to removal of part or all of an occipital lobe.

Occipital lobe lesions may be responsible for deviation of the eyes due to interference with the optic fixation reflexes.

Total blindness results from removal of the occipital lobes. Removal of one occipital lobe results in hemianopia which may or may not be characterized by "sparing" of the macula. It is our concept that the macular fibers do not cross after reaching the geniculate body, and that Verhoeff's[39] explanation for "sparing" is correct in all probability. He has pointed out that interference with the optic fixation reflexes may account for sufficient unsteadiness of fixation so that "sparing" results; in anteriorly situated lesions where "splitting" is encountered the optic fixation reflexes are not influenced.

Posterior injury of the occipital lobes produces central scotomas as shown by Holmes, and later by Greear and McGavic.[40] The central field defects have usually been associated with other field defects.

Homonymous quadrantic defects have come to be recognized as indicative of a radiation lesion but not necessarily a lesion of the occipital lobe. Complete loss of the lower visual fields, or homonymous quadrantic defects in the lower fields, have been observed to result from trauma. With penetrating injuries such loss of upper visual fields must be rare because the injury which produces them in this instance would penetrate dural sinuses and death would occur immediately.

Feigenbaum and Kornblueth[41] described ring scotomas in the visual fields as a result of injury to the occipital lobes. Greear and McGavic described bilateral homonymous hemianopia as a result of war injury. Holmes[42] charted completely congruous homonymous field defects originating in injury to the occipital cortex. From this brief recounting it would seem that the field defects associated with occipital lobe injuries may vary widely; they are congruous and, of course, homonymous.

We wish to draw attention to a group of cases seen in civilian practice which may be compared with cases seen as a result of war wounds. In cases in which air is injected into the posterior horn of the lateral ventricle there may be loss of vision which it would seem obvious must be attributed to involvement of the occipital lobes in large part.

In such cases we have observed almost complete blindness as a temporary phenomenon, bilateral homonymous hemianopia, and homonymous paracentral scotomas. In the cases with which we are familiar the visual defects and associated visual field changes have always cleared in greatest part, usually completely. These cases are comparable with other traumatic cases since trauma, even though elective, initiated the symptomatology. Again, similar to the traumatic cases, the initial loss of visual field is much more pronounced than the final field defects.

It was stated in the first paragraph of this paper that lesions involving the visual association pathways are not considered in any detail in this paper. The subject is extremely complicated and contentious. However, we may point out that alexia (word blindness) and object blindness (mind blindness) are each reported to have arisen as the result of occipital lobe injury. They are closely related affections or different degrees of the same type of involvement.

Convergence and divergence paralysis. We have seen what seemed to be examples of convergence and divergence paralysis in cases of head injury. Convergence paralysis has been observed on several occasions, usually as a late result. Divergence paralysis occurs less frequently. The diagnosis of divergence paralysis invariably had been made with some misgiving.

It is our belief that convergence and divergence palsies resulting from trauma, or from any cause, do not prove or disprove the existence of supranuclear centers concerned with the indicated capacities. All supranu-

clear centers, so-called, are theoretical and have not been demonstrated anatomically; they make possible visualization of associated ocular movements.

Immediately after trauma has occurred to the head, sometimes when it has been mild, there is incoördination in the movements of the eyes amounting to dissociation. Usually as the patient recovers the eyes become parallel, or, less often, muscle palsies develop.

With severe head trauma, divergence of the eyes is commonly observed during the period of unconsciousness. When such divergence is associated with dilated pupils the prognosis is grave.

Observation of injury cases does not clarify the situation as regards cortical control of convergence and divergence. However, it is quite certain that such control exists. Divergence of the visual axes during deep sleep, deep anesthesia, and following trauma supports this concept.

Cortical Blindness

Mention has already been made in this paper of bilateral homonymous hemianopia, which, in the absence of "sparing of the maculas" amounts to cortical blindness in many instances. There are several prerequisites to the diagnosis of cortical blindness. As enumerated by Marquis[43] these are: (1) Complete loss of all visual sensations including loss of appreciation of light and dark; (2) loss of lid closure reflex on exposure to bright light and threatening gestures; (3) retention of pupillary response to light stimulation, and on convergence; (4) normal retinas on ophthalmoscopic examination; (5) normal motility of the eye.

In cases of cortical blindness there may be hemiplegia, sensory disorders, aphasia, and disorientation, and consequently the diagnosis often is difficult. Not uncommonly individuals who are quite blind maintain that they can see; this is known as anosognosia.

Cortical blindness undoubtedly occurs as a result of injury, but it occurs infrequently in its complete form as defined above. In cases of blindness, partial or complete, following injection of air into the posterior horn of the lateral ventricle it seems probable that there is a degree of cortical blindness. In such cases blindness may be the only symptom. The fact that such patients recover in almost all instances is proof that there has not been death of cells. It seems probable that spasm of the posterior cerebral arteries may account for such blindness in many instances.

Visual Hallucinations

We have had little or no experience with visual hallucinations as a result of trauma. Weinberger and Grant[44] concluded that visual hallucinations have no value in topical diagnosis. They found that they were associated with lesions involving the optic pathways at many levels. They concluded that they represented psychologic phenomena involving the total integrative activity of the mind, and depended upon constitutional factors and not on cortical psychic organization. Our experience points to temporal lobe involvement when hallucinations are "formed" and to the occipital lobe when they are sensations, such as lights.

BRAIN-STEM LESIONS

Closed injuries to the brain produce widespread multiple, small hemorrhagic petechias. If the hypothalamus, midbrain, and pons are traumatized, hyperthermia, tonic fits, and respiratory distress are seen. The tonic fits are spontaneous or follow painful stimuli. Their presence gives a grave prognosis since when they appear the injury is rarely survived. Tonic neck reflexes are sometimes present.

Hemorrhages and edema about the aqueduct of Sylvius may occlude it, producing acute hydrocephalus. Many of the incoördinated eye movements and transient cranial nerve palsies which are associated with injury may be so produced. Frequently multiple small hemorrhages in the brain stem

are the only postmortem finding in patients who die as a result of head trauma.

Cerebral edema produces prolonged unconsciousness and many deaths. This is particularly true when the vital centers at the base of the brain are involved. Trauma to the cerebral hemispheres may result in a similar symptomatology as a result of herniation of the temporal lobes through the tentorium and of the cerebellum through the foramen magnum.

Because of such herniation the respiratory centers and other vital centers in the pons and medulla are compressed, thus resulting in prolonged coma or death. Under such circumstances, neurologic findings are the result of a combination of direct pressure, indirect pressure, acute hydrocephalus, and anoxia. Frequently it is quite impossible to state what produces any particular symptom.

Recently Kremer, Russell, and Smyth[45] have described several cases of severe head injury with damage about the aqueduct. They found that ataxia, incoördination, and prolonged loss of ability to speak were outstanding symptoms.

Ocular Signs of Brain-Stem Lesions

Frequently it is impossible to determine the precise site of the lesions which are responsible for incoördination of the eye movements in cases in which there has been injury to the base and presumably injury to the brain stem. It is our belief, however, that injuries to the brain stem are productive of transient ocular muscle palsies in a large percentage of cases of head injury in which recovery occurs.

Ptosis, either unilateral or bilateral, is not an uncommon finding. Certainly it occurs more frequently than definite conjugate deviation of the eyes or pronounced weakness of conjugate movement. In a majority of cases of injury to the brain stem the incoördination of the extraocular muscles is not pronounced. Probably when pronounced paralyses occur with lesions at this level the patient rarely survives.

Usually it is impossible to differentiate between nuclear and intranuclear lesions in such cases on the basis of examination of the eyes. Nuclear lesions involving the third nerve can be predicted with some degree of certainty, certainly not lesions involving the fourth and sixth nerves unless, with the sixth, there is an associated seventh nerve palsy.

Conjugate deviations of the eyes which originate in brain-stem lesions, notably in the pons, tend to be permanent as compared with deviations which originate in lesions of the hemispheres which tend to be transient.

Nystagmus and other involuntary movements of the eyes. Not uncommonly following trauma to the head there are involuntary coördinated movements of wide amplitude which resemble searching movements. These often come on as consciousness is returning. They are transitory and of no localizing significance.

In a small percentage of cases there is jerky nystagmus of wide amplitude seen in individuals who, while conscious, invariably vomit and complain of severe dizziness and unsteadiness. They present the picture of an acute labyrinthitis and usually suffer from fracture of the temporal bone in the region of the semicircular canals. In our cases such individuals usually have exhibited unilateral deafness.

Certainly, when following trauma nystagmus is present in association with deafness, the localization is obvious; there has been fracture of the temporal bone or damage to the vestibular apparatus.

In other injury cases when nystagmus persists the nystagmus probably points to brain-stem damage. Nystagmus which may be dependent on interference with optic-fixation reflexes is a very uncertain affection.

4. MISCELLANEOUS CONDITIONS

FAT EMBOLUS

When head trauma occurs, other parts of the body are often severely traumatized. Particularly when the long bones are fractured,

fat emboli may complicate the neurologic status. The lesions are produced by free liquid particles of fat in the blood stream. These particles plug the capillaries and small veins producing focal areas of necrosis.

The injury which produces fat emboli may be mild or severe. Fractures of bones, jarring of the skeleton, and trauma to the subcutaneous and intramuscular fat and to fatty visci sets liquid fat free. If there are severed veins in the vicinity, the fat may be forced into them. Usually there is a latent period of 48 to 60 hours before the appearance of symptoms, which, however, occasionally appear within 30 minutes.

Microscopic sections of the brain shows capillaries and the smaller vessels filled with fatty globules. Around plugged vessels there is an area of necrosis surrounded by a ring of hemorrhage. All parts of the brain are affected.

Vance[46] reported fat emboli in the lungs and kidney in 102 of 104 fatal traumatic cases. However, fat emboli were severe in only 11 cases and were considered as productive of the fatal termination in three instances.

The earliest symptoms are dyspnea, restlessness, tachycardia, and precordial pain. Then there is insomnia, memory disturbances, disorientation, and delirium. Stupor and coma develop in the terminal stages. As the coma deepens there is rigidity and tonic convulsions. In the terminal stages the muscles become flaccid and there is loss of sphincter control. Death due to respiratory failure supervenes about 1 to 4 days after the onset of coma.

Fat emboli in the retina are observed infrequently, but in all probability they are present more frequently than reported cases would suggest. Certainly they are not usually looked for in cases of trauma, or in fracture cases. Our experience is limited to a single case in which there was no history of trauma to the head. There were no visual symptoms suggesting the presence of retinal fat emboli. The patient, a young girl, had suffered a

fracture of the tibia, and a member of the house staff on doing a routine ophthalmic examination, detected the retinal changes which were observed several days after the accident occurred. Within 2 or 3 weeks the retina had become entirely normal. At no time had there been any reduction of visual acuity.

Retinal fat emboli appear as patches of white semihard exudates situated in the superficial retina about the posterior of the eye. In the single case we have studied the accumulations were circular. Some were almost as large as the disc, others were much smaller. In one instance, an underlying vessel was hidden from view. Most of the patches were well away from the retinal vessels. In our case there was gradual disappearance of the patches without development of scar.

CARDIAC RESPONSES TO INJURY TO THE HEAD AND FACE

Firm pressure on one or on both eyeballs slows the normal pulse rate and frequently reduces the rate of an auricular tachycardia. This response is known as the oculocardiac reflex. Often it is associated with a sensation of faintness and nausea.

It has been assumed that there is a reflex arc connecting the fibers of the ophthalmic nerve with the nucleus of the vagus. Pressure on the eye, or perhaps pain in the eye, or pressure within the orbit, sets up a train of action which ultimately stimulates vagus fibers thereby producing an inhibitory action on the heart, gut, and vasomotor tone. Exact connections between the fifth and tenth nerves have not been demonstrated histologically. The reflex has been observed as a physiologic phenomenon from pressure of the fingers, also as a result of intraocular infections, intraorbital hemorrhages and injections, and blows on the face which produce bruising and edema.

It immediately becomes apparent that the presence of the oculocardiac reflex in an individual who has suffered an injury to the

head may cause confusion as regards the diagnosis. Recently we observed a child who was struck just below the eye with a baseball bat. He was brought to the hospital to have a superficial laceration of the cheek treated.

When he was examined it was noted that he had an enlarged, oval pupil on the side of the injury. The pupil did not react to light either directly or consensually; there was a small amount of blood staining of the lower eyelid and it was thought there might be mild intraorbital hemorrhage. The pulse rate varied from 54 to 60 beats per minute.

He was observed for several hours without any change in his pulse rate, or any change in the abnormal pupil. On the following day his pulse rate had increased to 64 to 68 beats per minute. On the second day after the accident occurred the pulse rate was again within the range of normal for his age, 76 to 80 beats per minute. The child was not unconscious at any time.

Bradycardia seemingly present as an oculocardiac reflex may last for several days. In a child who had been kicked in the face over the lateral wall of the orbit, there was pronounced orbital hemorrhage with proptosis; there was pronounced limitation of all extraocular movements but no paralysis of any muscle. There was slight clouding of consciousness, and complaint regarding headache. There was severe nausea and occasional vomiting. The respirations were 16 to 24 per minute, and the pulse rate was 48 to 56 beats per minute. The patient was up and walking about. The pulse rate persisted essentially unchanged for four days and then periods of normal rhythm (70 to 76) developed.

It seemed as if the sinus node was being either stimulated or released from the control of the vagus intermittently. During this time, the orbital hemorrhage was subsiding and the ocular movements were improving. By the time the heart had resumed its normal rhythm, the orbital condition had almost completely cleared. The child was lucid at all times.

Knowledge regarding the occurrence of the oculocardic reflex is important in evaluation of head injuries. The slow pulse rate suggests increased intracranial pressure due to a subdural or extradural hemorrhage, or cerebral edema. However, the history of injury about the eye, and physical findings limited to the eye and orbit will usually allow one to come to the proper conclusion. In cases of doubt, the patient should be carefully observed in a hospital until there is no question about the diagnosis. It is to be recalled that the state of consciousness is of utmost importance. Usually the pulse rate is not significantly slowed without some impairment in consciousness.

Another phenomenon that we have noted in a few patients with basilar fractures or injuries to the base of the brain is periods of pulsus bigeminus. This may persist in short bursts for several days. Turning or otherwise stimulating the patient will frequently abolish the rhythm. Nurses checking the pulse of such individuals may report 30 to 40 beats per minute since every alternate beat is missed at the wrist.

The mechanism responsible for pulsus bigeminus is not at all clear. It may be related to the oculocardiac reflex. It may be due to abnormal stimuli applied to the hypothalamus. The electrocardiogram shows periods of extra systoles alternating with a normal rhythm. This has suggested that anoxemia was producing the extra systoles but clinically the patients were breathing normally and did not exhibit cyanosis.

We have observed this cardiac arrhythmia for as long as a week after injury. The periods gradually get shorter and shorter with longer intervals between them and eventually they disappear. In the cases we have studied the heart has been found to be normal.

Here again the significance of the cardiac rate must be understood. When it appears as an isolated finding, one is not justified in assuming that the patient is suffering from an intracranial hemorrhage or increased in-

tracranial pressure. The state of consciousness, the respiratory rate, and the temperature will be the best guides in evaluating the requirements for treatment.

ARTERIOVENOUS FISTULAS

Carotid-cavernous sinus fistulas are a relatively frequent sequelae of head injuries. The frequency is probably due to the unique anatomic situation, where an artery is actually surrounded by a venous sinus. This does not occur elsewhere in the body, and it is the only place inside the head where a large artery and vein lie in close approximation. Congenital intracranial arteriovenous aneurysms need not be commented upon here since they are developmental anomalies.

The site of injury producing a carotid-cavernous fistula is usually on the side of the head, about the lateral wall of the orbit or temporal region. Often the injury is so mild that consciousness is not lost. In nearly all cases there is a skull fracture that passes through the cavernous sinus. This may produce a tear in the wall of the carotid artery, or a fragment of bone may be driven into the wall of the artery.

The onset of symptoms is often rapid. The patient may notice a buzzing or humming noise in or behind the eye almost immediately, although it may be delayed. The examiner can easily hear a bruit with a stethoscope, usually loudest just over the eye. Detection of a bruit, even though it is pronounced, does not establish the diagnosis of carotid-cavernous fistula unless there is engorgement of ocular vessels and/or proptosis. The engorgement and pulsating exophthalmos may be delayed. We have on two occasions heard a bruit, one definite but soft, the other booming, in two patients neither of whom had a carotid-cavernous fistula.

Usually the conjunctiva becomes engorged and reddened within a few hours due to overfilling of the veins. In later stages it may become everted over the lower lid and we have observed alarming hemorrhages from such everted and swollen conjunctiva. Blood vessels of the sclera and lids also become overdistended within a short time.

Proptosis is delayed for several days but then proceeds quite rapidly. Following an initial increase, the exophthalmus progresses slowly. It is due to the overfilling of the ophthalmic vein. The globe pulsates synchronously with the heart beat.

Vision is good initially and the fistula may be present for many months before it is seriously affected. If the vision is poor or absent shortly after the injury, an additional lesion in the optic nerve or retina must be present. Ultimately, if the fistula is not closed as the result of operation, the visual acuity becomes low or is lost.

Papilledema in the affected eye is common according to Dandy. It occurs late. This is due to the venous engorgement. Extraocular palsies may be present, either due to direct trauma to the nerves, or due to the aneurysm with its distended veins. These palsies are usually incomplete, and often the motion of the eye is limited as a result of proptosis rather than a nerve palsy.

Pain may or may not be present, and often it is delayed in its onset. Horner's syndrome may occur if the sympathic fibers are interrupted. This is difficult to detect in the late stages.

The condition may persist for many years. We have seen a patient who had a carotid-cavernous fistula for more than 20 years. Proptosis was extreme, and vision almost gone from the affected eye. There was advanced primary optic atrophy. The veins over the lids, forehead, nose, and face were greatly distended and pulsated. The patient remarked that on occasions, these had ruptured spontaneously and that blood had spurted several feet. The hemorrhage was controlled with difficulty.

Dandy[1, 47] states that in 10 percent of cases the proptosis is bilateral. This is due to a persisting circular sinus that unites the two cavernous sinuses. He also remarks

that the proptosis is usually on the same side as the fistula but occasionally is present on the contralateral side. The bruit, however, is always loudest on the affected side.

Rarely the onset of symptoms is delayed for a few months. This is probably because the fistula is small. Besides blunt trauma, we have seen a case produced by a stab wound, in which the knife went through the supraorbital fissure and penetrated the wall of the carotid.

The diagnosis is usually not difficult. A history of trauma, distention of the veins about the eye, proptosis, and bruit are characteristic. Absence of the roof of the orbit may produce displacement of the globe, but the venous distention and the pulsation synchronous with the heart beat are not found. Tumors of the orbit and arterial aneurysms may produce proptosis and some degree of venous enlargement but bruit is absent.

Ligation of the internal carotid artery both intracranially and in the neck "traps" the fistula; it produces a cure in the majority of cases. Where the aneurysm has been present for a long time, it may be necessary to ligate the external carotid artery in addition because of collateral circulation. Ligation of veins in the orbit was at one time the only operative procedure. Now it is done only when venous distention persists after carotid ligations have been performed. In especially persistent cases, Adson[48] has found it necessary to ligate the ophthalmic artery; to cure the proptosis completely, he removed parts of the ophthalmic vein.

INTRACRANIAL BLEEDING

Intracranial bleeding is perhaps the most important complication of an acute head injury, and a fatal outcome may be due solely to bleeding that has resulted from trauma. The suspicion, detection, and evaluation of signs that hemorrhage may produce are highly important because prompt treatment is often life saving.

Blood may escape and collect in the fol-

lowing places: (1) Extradural space, (2) subdural space, (3) subarachnoid space, (4) subpial, (5) intracerebral, (6) intraventricular.

It is unusual for bleeding to develop at only one of these locations but it is common that one site may be the predominant site of hemorrhage while bleeding elsewhere is relatively unimportant.

For example, with a blow on the temporal region, a large extradural hematoma may form. Small subpial and intracortical hemorrhages in the temporal lobe may be produced at the same time but these do not change the clinical picture, or the treatment.

Each of the above subjects will be treated separately but it should be understood that, especially with severe injuries and compound fractures, any or all types of hemorrhage may occur simultaneously.

1. Extradural Hematoma

Bleeding from a ruptured middle meningeal artery or its branches is the usual cause. Rarely bleeding from the other meningeal arteries or bleeding from bone may be vigorous enough to produce a significant collection of blood.

The trauma may be severe or slight. A localized injury to the temporal region, such as a blow from a blackjack, falling on a stone or curb or against a railing or step, is frequently sufficient to shear the middle meningeal artery.

Factors that permit the shearing of the artery are: (1) It is embedded in a groove in the bone so that a minor deformation of the contour of the skull may rupture it, and (2) the artery converges from the bone at right angles which permits easy shearing with small movements of the dura.

It has often been emphasized that a relatively mild injury has been sustained perhaps followed by a brief period of unconsciousness. There is then a lucid period for a varying number of hours followed by a return of drowsiness, loss of consciousness,

Jacksonian convulsions, and perhaps other localizing signs. While this history is not unusual, many cases never have a lucid period, so that deepening unconsciousness and the appearance of fresh neurologic signs are just as important.

The rapidity with which extradural hematomas may form make it an immediate surgical emergency. Usually the bleeding is sufficiently brisk to manifest itself within 1 to 6 hours. Only occasionally do symptoms first occur after 12 hours but we have seen two instances in which there were insufficient symptoms to lead one to suspect extradural bleeding for 3 days and 1 week respectively.

Besides the onset of drowsiness the appearance of facial twitches followed by focal convulsions involving the face and hand are early signs. There may be weakness of the facial musculature or of the extremities on one side of the body but these are always mild. The order of appearance of the weakness is of extreme importance. It is always face, arm, and finally the leg.

Ocular signs are of the greatest importance. Very early one may note sluggishness in the pupillary light reflex on one side. Later inequality develops. The dilated pupil soon becomes fixed to light. Ptosis is occasionally noted. It never is complete. While the dilated pupil is frequently on the side of the hematoma this is not invariable. Usually the patients have become so drowsy and uncoöperative that the ocular movements cannot be adequately tested. Not infrequently there is divergent strabismus. At other times coarse searching-type movements are noted. Papilledema is absent at first but occasionally it develops within 24 hours and usually is present in some degree thereafter. Dr. A. C. Woods and Dr. W. E. Dandy observed *development of papilledema within 3 hours.*

Other signs of increased intracranial pressure make their appearance rapidly. Most prominent is noisy, difficult respiration. By this time, the patient responds only to the most painful stimuli. When both pupils become dilated and fixed, the terminal event is not far distant.

Since many of the signs and symptoms discussed above are not pathognomonic for extradural bleeding, multiple bilateral diagnostic trephinations should be used freely in cases of doubt. The procedure is easily done under local anesthesia and is harmless. It is better to trephine many cases than to procrastinate too long and lose a patient with this easily remedied condition.

2. Subdural Hematoma

This condition varies according to acuteness and age of patient. Each type requires separate description. They are (1) acute, (2) chronic, (a) occurring in infants, (b) occurring in adults. The acute form is almost always found in association with other types of intracranial bleeding, frequently with severe injuries. Even after evacuation the mortality is high. In contradistinction, the chronic variety is almost always found in "pure culture" and the chances for survival following removal are excellent.

Acute. Bleeding into the subdural space after a severe injury may come from several places. The veins passing from the cerebral cortices to the dural sinuses may tear and cause a profuse hemorrhage. Vessels may also be ruptured by indriven bony fragments or during the process of a contrecoup injury.

Frequently acute subdural hematomas are thin. Associated conditions such as subarachnoid hemorrhage, cortical laceration, and cerebral edema occur concurrently, and the clinical picture presented by the patient is not characteristic. When found at operation or autopsy, it is difficult to say which of the conditions produced any given symptom.

Occasionally, however, these hematomas become massive, and cause marked compression of the brain. They may extend from nasion to inion and are not infrequently bilateral. At operation 200 to 300 cc. of blood

may be evacuated from a single side. Death is no doubt directly caused by the bulk of the hematoma. It has been our experience, however, that after the removal of the blood, extensive injury to the brain is almost always uncovered.

Even these massive hemorrhages frequently fail to produce localizing signs. The patient is usually deeply unconscious, often not arousing from the time of the injury. Signs of medullary compression such as difficult and irregular breathing may be the first evidence that the patient is losing compensation. Tonic fits may be seen but Jacksonian convulsions are uncommon unless there is a cortical lesion in addition. In the later stages a mild hemiparesis, or bilateral pyramidal tract signs, may appear.

Eye signs are varied, unreliable, and not characteristic. The usual divergence of the eyes and dilatation of the pupils seen with unconsciousness is common. Sometimes the pupils are small and react sluggishly to light. They may be unequal but rarely markedly so. Since the bulk of these patients are unconscious and cannot coöperate, evaluation of ocular signs due to midbrain and medullary compression are difficult.

Papilledema is extremely rare since patients with significant acute subdural hematomas rarely live more than 48 hours unless treated. In our experience preretinal (subhyaloid) hemorrhages occur in approximately 25 percent of these cases. Almost always there is an associated subarachnoid hemorrhage.

Small subdural hematomas of a few millimeters in thickness found either at operation or autopsy probably produce no special symptoms and are not responsible for the patient's condition.

Chronic subdural hematomas in adults. These collections of blood present quite a different clinical picture from those discussed above. Often it is impossible to connect them accurately with trauma. They occur very rarely below the age of 20 years, except in infancy. It is noted that they are most frequent in the 4th, 5th, and 6th decades of life. They are found 6 to 8 times more frequently in men.

Since chronic subdural hematomas have never been produced experimentally, the sequence of events in their formation and the course they pursue is inadequately understood. It is agreed that the trauma responsible for the initial bleeding is often exceedingly mild and that there may be a latent period without symptoms of from a few weeks to several months. Some authors believe that all the bleeding occurs at the time of injury while others present evidence to show that the hematoma increases its size as time passes. Rarely the mass calcifies and produces symptoms years later.

Sometime during their course, membranes form around the hematoma. The outer is thick and vascularized while the inner is thin. The outer membrane can be easily stripped from the dura but leaves a mass of bleeding points. In our experience the inner membrane can rarely be stripped from the pia without causing considerable damage to the underlying vessels and cortex.

The signs produced by chronic subdural hematoma are exceedingly variable, and they may simulate almost any intracranial condition. There may be the usual symptoms of intracranial pressure as headache, bradycardia, vomiting, drowsiness, and unconsciousness. Dandy emphasized that head pain as distinguished from headache may be a feature. Meningeal signs such as a stiff neck and a Kernig's sign may be present. Evidence of local pressure such as hemiplegia, aphasia, cortical sensory disturbances, and rarely convulsions may be produced. There are no characteristic signs. Lumbar punctures almost always yield normal spinal fluid often under normal pressure. In an adult who has suffered a head injury, and presents obscure signs suggesting brain injury, diagnostic trephinations and ventriculograms should be utilized.

In contrast to acute hematoma, ocular signs are fairly frequent and important. Papilledema may be present but is found in only about 17 percent of patients (Govan and Walsh[49]). It is precisely the same type that is observed in cases of neoplasm. It probably develops late in the course of the disease but sometimes the changes of the nervehead suggest that the papilledema is old. If of long standing, secondary optic atrophy may result. In a few instances pronounced loss of vision has occurred rapidly.

Pupillary changes are important in the diagnosis of subdural hematoma, but frequently the pupils remain normal. A dilated and fixed pupil, or a slightly enlarged pupil which reacts sluggishly to light, suggests a hematoma. Pupillary dilatation was found in only 10 percent of cases surveyed by Govan and Walsh but in about half the series reported by Kennedy and Wortis. Undoubtedly pupillary dilatation results more frequently from extradural than from subdural hematoma. We have observed unilateral dilatation of a pupil in a case of bilateral subdural hematoma.

Incomplete ptosis is relatively common and is almost always unilateral. It is usually on the side of the lesion but may be contralateral. Complete paralysis of the third nerve has not been recorded so far as we are aware. Except for the pupillary paralysis and ptosis the nerve remains intact. Unilateral, and occasionally bilateral, involvement of the sixth nerve is seen in a few cases and is probably due to the generalized increased intracranial pressure. Rarely is the fourth nerve involved. We have seen conjugate deviation of the eyes away from the side of the lesion. Since the deviation was persistent, it was thought to be due to interruption of the supranuclear pathways in the hemisphere contralateral to the hematoma.

Visual field defects are found in a few instances. Maltby[50] described them in 11 percent of his series. The defects were homonymous and contralateral to a clot in all but one instance when it was ipsilateral. We have seen one instance of a homonymous hemianopia for color.

Total blindness with advanced optic atrophy is rarely seen and it follows long standing papilledema. Nelson[51] stressed the ocular signs due to brain-stem compression. Nystagmus, loss of convergence, paralysis and disorganization of gaze were noted. These were thought to be due to lesions about the oculomotor and abducens nuclei and about the posterior longitudinal bundles.

In most instances the ocular signs subside rapidly after evacuation of the clot. The ptosis and inequality of the pupils may disappear in a matter of minutes; likewise do the palsies, aphasia, and visual field defects. The state of consciousness improves rapidly although the patient may be confused for weeks. Papilledema subsides more slowly, often persisting for a month. Visual loss due to optic atrophy is irreversible as are some of the brain-stem symptoms described by Nelson.

Hematomas in infants. Hematomas are fairly common in infants under the age of two years. Here again, trauma is important but the injury may be mild and escape notice. Some authors believe that the bleeding may start during delivery. Among infants, the difference in frequency because of sex is not pronounced as it is in adults. The general state of nutrition seems more important. Rickets and scurvy may well be predisposing causes.

The incidence of bilateral hematoma is much higher among infants. This probably accounts for the relative prominence of signs of increased intracranial pressure and the paucity of signs of local pressure. Tense and bulging fontanels are of the greatest importance and are almost constant. Diagnostic subdural taps through the fontanels should be done in every case where there are signs of pressure. Lumbar punctures are also of extreme importance. In almost all cases there is blood or xanthrochromic spinal fluid. A slight elevation of temperature is present in about one third of the cases.

Convulsions are very common. Govan and Walsh noted convulsions in 91 percent of infants and only 4 percent in adults. Vomiting occurs in about one half of the cases, while drowsiness and irritability are even more frequent. Coma may be the presenting symptom in as many as one fourth the number of infants.

The ocular signs are generally the same as those described in adults, with a few exceptions. The incidence of papilledema is about the same or perhaps less. One important point is the presence of subhyaloid retinal hemorrhages. They are very common in infants and are almost never seen in adults with hematomas. The reason for this is not altogether clear. Govan and Walsh have pointed out the difference in anatomy along the superior longitudinal sinus in infants and adults. In the former the pial veins are almost unsupported as they enter the sinus. This permits easy tearing in the event of trauma and, since the arachnoid is also extremely thin, it is probably torn simultaneously. This permits blood to escape into the subarachnoid space, thereby accounting for the blood in the spinal fluid.

Subarachnoid Bleeding

Blood in the cerebrospinal fluid is a frequent finding in head injuries of more than moderate severity. While it signifies a fair degree of trauma and its presence makes the prognosis somewhat more grave, the bleeding itself rarely produces symptoms or sequelae.

The hemorrhage may produce signs of meningeal irritation, a rise in temperature, and is not infrequently associated with pre-retinal hemorrhages.

If the injury responsible for a profuse subarachnoid hemorrhage is survived, certain late phenomena may occur due to the plugging by the blood of the absorbing mechanism of the cerebrospinal fluid. This produces an acute communicating hydrocephalus, with the usual signs of pressure, papilledema, and cranial-nerve palsies.

When the condition is relieved either spontaneously or by operative measures, the signs and symptoms subside.

Intracerebral Bleeding

The most common form of intracerebral bleeding is multiple petechial hemorrhages. The clinical picture is usually that of concussion and the symptoms are not localizing. We have seen severely injured patients who exhibited divergent strabismus, horizontal nystagmoid movements, alternating dilatation and constriction of one or both pupils and, in the terminal stages, bilateral fixed and dilated pupils. In such cases one cannot be sure whether the signs produced are due to a localized lesion in the brain stem or generalized increased pressure. Even at autopsy this question is not answered. Individuals who survive such injuries may show certain changes attributed to lesions about the aqueduct of Sylvius. These have been discussed previously.

Large collections of blood sometimes form in the frontal and temporal lobes. Should the patient survive the acute phase of the injury, these intracerebral hematomas may produce signs typical of those of any intracranial neoplasm in the same position. Many absorb slowly and leave porencephalic cysts, their presence being asymptomatic. Large intracerebral hematomas are rare complications of head injuries. If they produce signs of pressure, they should be evacuated.

The Eyelids and Conjunctivas and Trauma

It is generally known that ecchymoses develop in the eyelids and conjunctivas as the result of trauma about the orbit which results in a "black" eye, and as a result of fractures in the base of the skull. Similar ecchymoses may occur under other circumstances when their origin is not easily understood.

When trauma is directly applied to the eye and orbit, as, for example, a blow from a fist, there is the development of a "black" eye. Immediately after the blow has been struck a purplish-red color of the eyelids and

extreme redness of the conjunctiva appear. After a day or two, the color changes to purple, then to green, then to yellow, and finally to normal.

Associated with discoloration of the eyelids and conjunctivas there may be dilation of the pupil; usually such a pupil is irregular in shape and sluggish in its response to light. There may be intraocular damage, such as detachment of the retina, tearing of the choroid, dislocation of the lens, or dislocation backward of the optic nerve, but such injuries are uncommon and as a rule a "black" eye is properly regarded as a trivial injury.

When there is a fracture in the anterior fossa extending into the orbit, the blood is said to extend along the torn dura and bone. It becomes visible several hours or even several days after the injury. Often the lower lid contains more blood than the upper and frequently there is "butterfly" distribution of the blood staining. The color is purplish rather than red.

Blakeslee[52] in studying 610 fractures of the skull found eyelid and conjunctival hemorrhage in about 17 percent of the cases. In some instances he observed that blood reached the eyelids when the fracture was situated far posteriorly. In such instances he visualized the blood extravasations as due to the explosive action of the force which had produced the fracture.

In several cases of fracture of the middle fossa, we have observed characteristic blood staining of the eyelids. In cases described by Greear and McGavic there were massive intraocular hemorrhages when bullet wounds were situated far posteriorly; in such cases undoubtedly there were extensive subarachnoid hemorrhages.

Hamilton Bailey[53] made a useful differential diagnosis between "black" eye and hemorrhage into the eyelids and conjunctivas as a result of fracture of the base, and his observations conform largely to ours.

1. In fracture of the base the extravasated blood is limited sharply by the pal-

pebral fascia to the orbital margins, and thus it tends to be circular. In "black" eye there is no such limitation.

2. With fracture of the base the discoloration of the conjunctiva is purplish from the commencement; whereas, with "black" eye it is beefy red. With "black" eye, hemorrhage is in the conjunctiva and the mass of hemorrhage moves when the conjunctiva is moved; in fracture of the anterior fossa the hemorrhage is subconjunctival.

4. With a conjunctival hemorrhage associated with "black" eye there is a posterior limit to the extravasation; whereas, in fracture of the anterior fossa there is no such limit and the hemorrhage tends to be fan-shaped with the handle of the fan toward the iris.

5. With fracture there is a parallelism between the edema and the amount of blood in the eyelids; that is, the greater the edema the greater amount of blood by inspection; with "black" eye with pronounced edema there is relatively little blood.

6. With fracture, the blood in the eyelids almost always is first seen at the medial border of the lower lid and gradually suffuses along the lids. It rarely joins the lesser suffusion in the upper lid at the outer canthus.

7. If the eyelids are everted the conjunctivas in a case of fracture usually are clear; whereas, with "black" eye they are edematous and discolored.

Ecchymoses in the eyelids following fracture of occipital bone. As an unusual example we may cite the case of a woman who fell forcibly into the sitting position. She developed the ocular picture of fracture of the base.

Ecchymoses in the eyelids following cranial operations. We have observed that following many transcranial operations there is pronounced edema of the eyelids and hemorrhages occur in them. The mechanism accounting for such extravasations is unclear. On first thought it would seem likely

that such hemorrhages resulted from taking down of the bone flap, but in many cases this can scarcely apply. The extravasation in many such cases is precisely that which is seen associated with fracture of the base. We have observed such extravasations following prefrontal lobotomy and following a transcranial operation when the subdural space was not entered.

We do not have an explanation for the ecchymoses which occur as the result of transcranial operations in which there has not been gross trauma applied to the skull, and such extravasations seem particularly mysterious when the operative effort has been directed to posterior aspects of the skull. It seems questionable that the explanation concerning fracture of the base, namely disruption of the periosteum, is valid in consideration of the fact that such lid extravasations occur under many circumstances when the base is intact.

PNEUMOCEPHALUS

Following fractures of the skull, air may collect extracranially beneath the galea, or intracranially. Both of these conditions are rare.

Extracranial aeroceles. Fractures through the frontal sinuses or mastoid cells may allow air to escape beneath the galea and strip the scalp from the skull. Slight increases in the intraoral pressure may be sufficient to elevate large portions of the scalp, since it is so loosely adherent to the pericranium.

The spread of the emphysema is limited by the attachment of the galea and consequently does not spread like subcutaneous emphysema elsewhere in the body. Treatment is simple, since only aspiration is required. One should not be misled in the diagnosis.

The soft fluffy tumor in which crepitation can be felt is typical of gas in the soft tissues. Gas gangrene can be easily eliminated since it is practically unknown in the scalp and an infection necessary to produce so much gas would also give rise to alarming systemic symptoms, while pneumocephalus is often asymptomatic.

Intracranial aeroceles. As pointed out by Dandy,[54] air may collect in the subdural space, subarachnoid space, in the brain substance, and in the ventricular system. Subdural collections of air are very unusual. These are small since the subdural space is only potential and considerable pressures are required to expand it. Subarachnoid filling must be accomplished by a break in the membranes in one of the cisterna.

Most cases of pneumocephalus are the results of fractures that pass through the frontal or paranasal sinuses. In these regions the dura is thin and adherent, so that it is easily split. Occasionally breaks in the region of the middle ear and mastoid cells may allow air to escape inside the head. Gunshot wounds, compound fractures, and stab wounds, especially in the occipital region, may produce a fistulous opening, producing pneumocephalus. Besides trauma, ostemas of the skull, syphilis, tuberculosis, and cancer may erode the coverings of the brain. Mild trauma under these circumstances may produce a fistula.

A case in which gas was demonstrated in the orbit and frontal lobe following a puncture wound of the lid by a lead pencil was reported by Slaughter and Alvis.[55] The "lead" apparently was pushed through the orbital roof into the frontal lobe. An orbital abscess followed which was drained with eventual complete recovery. The gas may have been air, or may have been generated by the bacteria producing the abscess.

Courville[56] remarked that the intracranial collections of gas are air less oxygen, since the latter is rapidly absorbed. He also stressed the necessity of having a loose flap of dura producing a valvelike action to trap the air inside the skull.

Symptoms may be present almost immediately following the trauma or may be delayed for months. The reason for the latter is not clear, but since basal skull fractures are very slow to heal, a sudden increase of

intraoral pressure during sneezing, coughing, and so forth, may rupture the overlying meninges and allow the ingress of air.

The complaints of the patient may be mild. Often there may only be a complaint of a "swishing or sloshing" noise in the head. This is almost characteristic of air in the ventricular system. On the other hand, there may be symptoms of increased intracranial pressure, with severe headache, dizziness, nausea, vomiting, hyperthermia, and unconsciousness. If the pressure is prolonged, papilledema develops.

The pressure may be constant or spasmodic. In the latter instances, the temporary rises are brought about by coughing, sneezing, straining, and so forth, and are undoubtedly due to the ball-valve action of the tissues in the fistula. There is severe head and face pain in sneezing, sudden nausea, and even temporary lapses of consciousness.

The diagnosis is usually easy to make. Evaluation of the patient's story of sudden pain and swishing noises in the head are sufficient. Patients with intermittent rhinorrhea are very good candidates for pneumocephalus. X-ray studies will demonstrate the presence of gas inside the skull, and spontaneous ventriculograms have been noted frequently.[57]

Treatment should be conservative in the beginning. The patient should be put at rest and observed. Penicillin and sulfonamides should be given prophylactically since meningitis or intracranial infections are real dangers. If a compound vault fracture is present, it should be treated in the usual manner. Most of the cases are benign and the fistulas soon close. The gas is then rapidly absorbed.

Occasionally symptoms remain, or those of increased pressure progress. In these cases surgery is indicated. The tear in the dura should be closed, with a graft if necessary. The skull fracture may be treated at the same time, by elevation of a depression, removal of loose fragments, and so forth. Treatment should not be long delayed in cases of intracortical aeroceles as persistent pressure may cause considerable cortical damage.

The end results are usually good especially if chemotherapy is started promptly and if operation is not long delayed in cases that do not show rapid absorption of the air.

SUBCUTANEOUS EMPHYSEMA

Air may be forced into the subcutaneous tissues in large amounts following puncture wounds of the chest. There is probably a bellowslike action of the lungs which forces air into subcutaneous tissues through a fistula that has a ball-valve action. Once into the loose subcutaneous tissue, there is almost no limit to where the air may dissect. It is restrained only by the tough attachment of the skin in the palm of the hands and soles of the feet, and by the galea at the edges of the skull. We have seen a patient who within two hours following a closed injury to the chest that produced several fractured ribs, had subcutaneous collections of air over the entire body except the finger and toe tips and the scalp. The eyelids were so full of air that the eyes were swollen shut.

Besides chest wounds, generalized emphysema may follow the puncture of almost any air-containing viscus. Tracheotomy and operation in the nasopharynx may allow the egress of air into the subcutaneous spaces. Brown and Hinton[58] report an instance following the operative resection of the large bowel. They mention cases following rupture of a peptic ulcer and a perforated sigmoid diverticulum.

Localized emphysema of the orbit may follow tooth extractions or operations in the paranasal sinuses. In both these cases the continuity of bone is broken and air is forced into the orbit. Linhart[59] has reported several cases following trauma about the nose or eye. Often this is mild, and not infrequently follows falls or boxing. We have seen it following stab and gun wounds about the eye, also after therapeutic injections about the eye and in the nose.

Air readily finds its way into the orbit when the lamina papyracea of the ethmoid is fractured. Increased intranasal pressure, as produced by sneezing and coughing, forcibly propels more air through the fracture. Thus air reaches the eyelids and the air is behind the septum orbitale.

In such cases, there is a unique combination of signs: proptosis and narrowing of the palpebral fissure. Emphysema of the lids with the air in front of the septum orbitale does not produce exophthalmos or pronounced narrowing of the palpebral fissure.[60]

The diagnosis of subcutaneous emphysema is not difficult to make. The soft swelling of the tissues, with crepitation that can be felt and heard, leaves no doubt about the presence of gas. Both in the generalized and orbital cases, there is usually a history of trauma or operation. X-ray studies of the orbit will demonstrate the air clearly, but fractures of bone are almost never seen.

It is of importance to realize that the firm attachment of the galea limits the upward direction of the air. As pointed out in the section on pneumocephalus, extracranial aeroceles are limited by the attachment of the galea and therefore do not involve the lids and orbit. Likewise air coming from below this attachment will involve the eyes but will not go into the scalp. If both are found two lesions must be present.

Gas gangrene is the only condition that may be confusing. However, patients with this condition do not show the rapid advance of gas in the subcutaneous tissues. In traumatic cases, the symptoms begin at once but, in gas gangrene, there is a delay of hours or days. Also the local condition of the wound, fever, tachycardia, pain, and cerebral signs of intoxication charasteristic of gas gangrene are missing in cases of subcutaneous emphysema.

Treatment is conservative, as far as the emphysema is concerned. Penicillin and sulfonamides should be administered to prevent infection. In the generalized cases, the swelling of the lids usually subsides within 72 hours, while in the localized orbital cases all get well within a week.

DIAGNOSTIC PRINCIPLES AND TREATMENT OF ACUTE HEAD INJURIES

Only the broadest principles can be mentioned here. Patients in shock should be treated for such at once. Then a history should be obtained. Since many patients are unconscious, this may have to be obtained from relatives, witnesses, or police. The type of injury received may be the largest clue as to what is going on inside the head.

The physical and neurologic examinations should be as thorough as possible. The results should be recorded, as changing signs, especially in the state of consciousness, are of the greatest importance. Associated injuries may need prompt attention and should not be overlooked.

It is rare that acute injuries require immediate operation. Since most patients will require careful watching, nurses properly trained are essential. Frequent determination of the temperature, pulse, respiration, and blood pressure are noted. The state of consciousness is most important and any changes should be noted and evaluated. The surgeon should often check on this point himself. The appearance or disappearance of neurologic signs should be watched for and recorded.

Besides these things, the unconscious patient needs constant attention to see that vomitus is not aspirated; that his temperature is controlled, either by keeping him warm if the temperature is subnormal; or by cooling him by fans, ice sponges, and so forth, if it goes about 104°C. An adequate airway must be maintained. An unconscious patient who has difficulty breathing should be suctioned frequently, an anesthesia airway inserted and, if necessary, intubated. Bladder catheterization may be necessary and the bladder should not be allowed to become overdistended.

Certain neurologic signs and symptoms, if present, or if they appear under observation,

require careful consideration since they may signify that a collection of blood of surgical importance may be forming. A steadily deepening unconsciousness, especially after a lucid interval, is very important. A prolonged period of unconsciousness without signs of rousing may be equally significant.

Anisocoria with a sluggish or fixed pupil very commonly means that a large hematoma has formed. This sign may be transient but that does not lessen its importance. The onset of facial convulsions later spreading to arm and leg is a sign of local irritation and often means that an extradural hematoma is present.

Generalized convulsions, especially in children, do not carry the same import. Usually they are produced by a local cortical laceration or blood in the subarachnoid space. "Tonic" or cerebellar fits mean brain-stem injury or compression and carry a grave prognosis. Not infrequently large subdural hematomas producing great increase of intracranial pressure account for this type of convulsion.

The onset of a hemiparesis, sometimes only evident in the face, or the appearance of unilateral clonus and the Babinski sign, may be of surgical importance when they occur in the presence of other symptoms indicating a rapidly rising intracranial pressure.

The respiratory rhythm is often a valuable guide to the state of intracranial compensation. A falling rate usually means increasing pressure. However, an irregular rate, with beginning cyanosis, retraction of the chest, and a honking noise due to a relaxed soft palate means that the medullary centers are becoming embarrassed. Occasionally this is the only sign of failing compensation, and we have seen several instances when this has been due to massive acute subdural hematomas. Diagnostic trephinations should be done promptly in the absence of other signs.

X-ray examinations have little importance in the immediate treatment of acute injuries. Most depressed fractures may be palpated.

The presence of linear fractures may increase one's suspicion that a hemorrhage of surgical significance is present, but operation should neither be delayed because of its absence nor rushed because of this finding. Before depressed and compound fractures and gunshot wounds are subjected to operation, an adequate X-ray examination of the head should be carried out.

The value of diagnostic lumbar punctures is open to question unless infection is suspected. The presence or absence of blood is of academic value, and the pressures are not reliable guides.

Diagnostic trephinations should be used freely in cases of doubt. They may be done under local anesthesia and carry no risk. Openings should be large enough to inspect the dura and cortex thoroughly. A small crown trephine makes excellent inspection holes. Openings should always be multiple and bilateral. Four holes in each side of the head are usually adequate, two about 2 to 3 cm. from the midline; one in the frontal and one in the parietal regions, and two in the temporal region; one in front and the other behind the ear. The ventricular system may be tapped at the same time and the fluid studied. The hemispheres may also be explored with a needle for intracerebral hematomas.

Ventriculograms, encephalograms, and arteriograms may be necessary in chronic cases. Their use during the acute stages of a head injury is not recommended.

Treatment is divided into operative and nonoperative. The bulk of cases falls into the latter classification. Rest, adequate fluids, chemotherapy and antibiotics, and mild sedatives are used. We have had no experience with the regimens of dehydration and repeated lumbar punctures and have not been impressed by the statistics cited by others. Convulsions are controlled with phenobarbital and intramuscular magnesium sulfate.

Operations are reserved for compound

and depressed fractures and hematomas. Compound fractures of the vault should be thoroughly debrided, cortical bleeding controlled, the dura repaired, and the scalp closed. This should be done as soon as shock has been controlled. The same holds true for gunshot and other penetrating wounds of the skull.

Depressed fractures should be elevated promptly. Although the bulk of the cortical damage is sustained at the time of injury, if the condition is not relieved, additional damage may be sustained during the period of edema and later during scar formation. While some neurosurgeons disagree on the necessity for elevation of all depressed fractures, especially those over "silent" areas, the risk involved is so slight it seems all should be repaired as soon as the shock has been controlled.

Linear cracks need no special care, other than that outlined above. When the fracture has passed through the ear or a sinus, the liberal use of antibiotics and chemotherapy is indicated until all drainage has stopped and healing has been completed.

Extradural hematomas when located should be evacuated promptly and the bleeding controlled. Most of these hemorrhages are produced by rupture of the middle meningeal artery. In every case this vessel should be located and traced to the foramen spinosum to be sure that it has not been torn. If the hematoma is evacuated promptly the prognosis is excellent. Frequently, the symptoms disappear within a matter of a few minutes. However, if operation is delayed, pressure on the vital centers may be so severe that unconsciousness persists for days and severe permanent cortical damage results. At times, death ensues despite the relief from pressure.

Subdural hematomas present a somewhat different problem. In the thin acute type, simple irrigation through burr holes is sufficient. If the hemorrhage is massive, it may be well to enlarge one of the openings suf-

ficiently so that the hemorrhage can be thoroughly and quickly evacuated. Any bleeding from torn cortical vessels can be stopped with the cautery at the same time.

Chronic subdural hematomas on the other hand often present a more difficult problem. These, too, can sometimes be evacuated through burr holes and the membranes allowed to absorb. The process may have to be repeated several times. A better method is to turn down a small flap so that the blood can be entirely removed. The outer membrane need not be stripped completely but the incised edges should be carefully cauterized to prevent oozing. Rarely can the inner membrane be stripped completely, and this should not be attempted if it is adherent to the cortex.

The hematomas in infancy can sometimes be cured by multiple aspirations through the open fontanel or by a burr hole placed beneath the temporal muscle. However, if fluid continues to reaccumulate after 3 or 4 taps, or if membranes are present, a small bony flap has proved satisfactory for the complete removal of the hematoma and at least part of the membrane.

Subarachnoid hemorrhages should be treated conservatively. The nuchal rigidity and fever produced by the blood may lead to confusion with meningitis. A diagnostic lumbar puncture will clear up this difficulty. Repeated drainage of the cerebrospinal fluid in an effort to draw off the blood has not seemed worth while.

Intracerebral hematomas of significant size are rare. If they present symptoms, they should be tapped and the blood drawn off.

Recently, some authors have advocated total removal of badly lacerated temporal and frontal lobes shortly after the injury. They point out that an internal decompression is obtained, and that convalescence is shortened by the removal of the mass of necrotic tissue. This seems a rather heroic measure, and in our hands has not been very successful.

In summary, operative intervention is only occasionally required in the treatment of head injuries, and is directed toward the evacuation of collections of blood and the repair of compound fractures. Subtemporal decompressions for increased intracranial pressure have questionable value.

SOME OBSERVATIONS ON MIOTICS*

EDWIN B. DUNPHY, M.D.
Boston, Massachusetts

The fact that so many different miotics are in use is perhaps an indication that the ideal one has not yet been found. During the past 15 years, tremendous strides have been made in our knowledge of the pharmacodynamics of the intraocular muscles, but there are still many gaps in our understanding of how miotics act and why they sometimes succeed in controlling increased intraocular pressure and more often fail to do so.

Therefore, it may be worth while to evaluate some of the miotics currently used, beginning with a brief review of the pharmacologic background.

PHARMACOLOGIC BACKGROUND

Although the possibility that chemical substances might mediate nerve impulses was suggested as far back as 1877 by Dubois-Reymond,[1] it was not until 1914 that Dale[2] brought forward his theory of the parasympathomimetic action of acetylcholine on the autonomic nervous system, and postulated the existence of an esterase to account for its brief duration and its breaking down into acetic acid and choline.

The classic experiments of Loewe[3] in 1921-1922 established the first proof of the release of chemical agents by nerve impulses and the fact that these substances act on smooth muscle causing it to contract. Due to the work of Feldberg,[4] Dale,[5] Chang and Gaddum,[6] and others it has become accepted that stimulation of parasympathetic nerves causes the liberation of acetylcholine at the myoneural junction. In similar fashion most sympathetic nerves act through the medium of epinephrine, the notable exception being those to the sweat glands.

The theory of nerve impulses being transmitted by acetylcholine at the myoneural junctions has been challenged recently by Nachmanson,[7] who suggests that this substance is responsible only for conduction. However, his views have not received universal acceptance.

Englehart,[8] in 1931, showed that impulses, passing along the short ciliary nerves, liberated a substance in the aqueous which had the properties of acetylcholine. This was absent when the ciliary ganglion had been removed beforehand. It was found to be greatly increased when the eye had been previously exposed to light, but it was absent in the dark-adapted eye, even after eserine had been instilled to destroy the cholinesterase.

The present belief is that acetylcholine exists in the tissues in an inactive, nondiffusible form. The nerve impulse changes this to an active and diffusible form which acts immediately on the hypothetical effector cell, but is thereupon quickly destroyed by cholinesterase. The inactive form persists as long as parasympathetic nerves remain intact.

The ciliary body has plenty of it except when the postganglionic fibers are cut. As the nerves degenerate, the acetylcholine disappears from the tissues but, as Cannon[9] has shown, the cells formerly innervated by the parasympathetic fibers then become abnormally sensitive to acetylcholine. This increased sensitivity to acetylcholine can develop within 24 hours. Its mechanism is not clearly understood.

CLASSIFICATION OF MIOTICS

We may divide miotics into two broad groups:† (1) Those which act directly on the effector cell in the iris muscle, and (2) those which act passively by inactivating or de-

---

† Since this paper was written a new group of miotics which block sympathetic stimulation adrenergic receptors has been introduced into ophthalmology by Christianson and Swan.

stroying cholinesterase and thus permitting the unregulated production of acetylcholine which stimulates the effector cell to activity.

Those in the first group are, for the most part, drugs closely related to acetylcholine, and merely supplement the normal stimulation which this chemical gives to the sphincter muscle of the iris. They are mecholyl, charcolin, and furmethide. Pilocarpine, an alkaloid, acts in similar fashion, and, like the others, is effective after nerve section and complete degeneration. Histamine also acts directly on the muscle and is a very powerful miotic, but it causes too much irritation to be of practical value.

The second group, which destroys cholinesterase and thus allows the uncontrolled production of acetylcholine, is probably the most powerful but not necessarily the most desirable. Examples of this group are eserine, neostigmine, the fluorophosphates, and a relatively new compound, tetraethyl pyrophosphate.

Miotics may be discussed under three main headings. (1) Their effect on the musculature of the iris and ciliary body. (2) Their effect on the vascular supply of the anterior segment and on the blood-aqueous barrier. (3) Their effect on the intraocular pressure.

I. Effect on musculature of iris and ciliary body

In general, any miotic, when dropped into the conjunctival sac, affects the iris sooner than the ciliary body, probably because it reaches the iris first and in higher concentrations. Thus miosis begins before any spasm of accommodation takes place.

The degree of miosis and accommodative spasm depends entirely on the intraocular concentration of the drug and the individual quantitative response. Some miotics produce relatively more cyclotonia in relation to miosis than others. We must always remember in comparing one miotic with another that usually the same degree of miosis can be accomplished by either, provided an ad-

equate concentration is brought to bear on the iris.

Factors affecting the intraocular concentration are the size of the drop used, the vehicle emyployed, the method of instillation, the permeability of the corneal epithelium, the physical properties of the drug, and its relative affinity for water or fat. With so many variables it is obvious that direct comparisons of one miotic with another must be carefully controlled to have any value.

The following observations on the various miotics are based on my own experience, and that of others.

Pilocarpine. The miosis produced by 1-percent to 2-percent pilocarpine is prompt and efficient, but lasts only for a day. In these same concentrations, pilocarpine usually causes a slight, but not unpleasant, stimulation of the ciliary muscle, and this fact has been made use of by some ophthalmologists in recommending the use of 0.25-percent solution before reading for certain young asthenopes with subnormal accommodation. I have found this useful on occasions.

However, certain individuals may react rather violently to pilocarpine, as little as 0.5-percent solution causing a marked miosis and ciliary spasm, but these are exceptions. On the whole I feel it is the most satisfactory miotic and can be used in much higher concentrations than was formerly thought possible.

For maximal miosis in glaucoma a 4-percent solution is frequently employed, and it can be used as high as 10 percent if the HCl salt rather than the nitrate is employed, since the former has greater solubility. The pH must be kept at 5 to 6 to avoid precipitation of the alkaloid. Long-continued use, even in moderate concentrations, occasionally causes a follicular conjunctivitis and the production of pigment synechias, but in my experience this is extremely rare. Pilocarpine is superior to eserine in this respect.

Acetylbetamethylcholine (mecholyl) is

poorly absorbed through the cornea and has very little effect on the normal pupil in anything less than 15-percent solution. I have attempted to remedy this by the addition of zephiran (1:3,000 solution) as a wetting agent, but without success. However, as Adler[10] has pointed out, the situation is different in a glaucomatous eye with high tension, where a 10-percent solution will constrict the pupil readily.

This apparent sensitivity to mecholyl in glaucoma is interesting. It may be that the choline esterases are interfered with in this disease as suggested by Friedenwald[11] and hence mecholyl is more effective than in normal eyes. Swan's[12] explanation is that the corneal-epithelial barrier is disturbed in cases with elevated tension and this enhances absorption.

Adler and Scheie[13] found that, although mecholyl in less than 15-percent solution had no effect on the normal pupil, a 2.5-percent solution sharply constricted the tonic pupil of Adie's syndrome. From this observation and from experimental work on cats, they concluded that the site of the lesion in tonic pupils is in the third nerve somewhere between the ciliary ganglion and the nerve endings in the sphincter muscle, and that the lesion partially destroys these fibers. Hence the pupil becomes permanently sensitized to acetylcholine and will respond to small concentrations of mecholyl which ordinarily would have no effect.

It has been my experience that in the dilated atrophied pupil of an old blind, glaucomatous eye, a 10-percent mecholyl solution will constrict the pupil moderately; whereas, in the dilated pupil of a complete third-nerve paralysis the same drug will have no effect. In the former case there has been damage to the postganglionic nerve-fiber endings in the sphincter muscle with some sensitization, but, in the latter, the preganglionic fibers are probably involved, hence no sensitization.

In glaucomatous eyes mecholyl usually causes more stimulation of accommodation than pilocarpine, but not as much as some of the other miotics. Since this drug is partially destroyed by cholinesterase upon reaching the aqueous, its action is brief, the miosis persisting for two hours only. Therefore, for practical purposes it should be used with one of the cholinesterase inhibitors, usually neostigmine.

A word of warning should be given on the use of mecholyl by retrobulbar injection, a method occasionally employed in acute glaucoma and in cases of sudden obstruction of the central retinal artery. I have seen three near-fatalities by this method of administration. Although the dose in each case was considered a perfectly safe one, the patients reacted very badly to it, going into circulatory collapse. It should never be given subconjunctivally unless there is, ready and waiting, a sterile syringe containing 1/100 gr. atropine. Mecholyl by injection is also contraindicated in asthmatics for fear of bronchial constriction.

Carbaminoylcholine (carcholin). This drug, formerly called Doryl, is another choline ester which is probably the most toxic and the most potent of the group. It has the advantage of not being destroyed by cholinesterase. Its miotic action is therefore prolonged, provided it is properly administered.

O'Brien and Swan[12] brought out the important fact that this drug is poorly absorbed through the cornea. Carcholin is of low surface-tension activity with high affinity for water, and low lipoid affinity—such drugs are poorly absorbed in aqueous solution since they tend to remain in their vehicle.[14] O'Brien and Swan[12] recommended the instillation of 1.5-percent solution of carcholin in an aqueous solution of zephiran (1:3,000) which reduces the surface tension of the cornea, possibly injures the corneal epithelium, and thereby enhances absorption.

In a more recent communication Swan[15] found that 1.5-percent suspension in anhydrous petrolatum penetrated best of all. By

this method carcholin has a relatively higher affinity for the corneal epithelial barrier than for its vehicle, and therefore passes through readily.

The accommodation is definitely stimulated by carcholin, O'Brien and Swan[12] finding an average of 1.18 diopters of false myopia produced by one drop of the above concentration as compared to an average of 0.5 diopter produced by 2-percent pilocarpine.

Furfuryltrimethylammonium iodide (furmethide) is a fairly recent drug, which is a strong parasympathetic stimulator, and which is not destroyed by cholinesterase. When used in 10-percent solution, its miotic action is prompt and it produces a moderate degree of cyclotonia. According to Owens and Woods,[16] it is more effective than mecholyl and prostigmin in acute primary glaucoma, especially in late cases, and is slightly more effective than pilocarpine (2 percent) in chronic primary glaucoma. Although I have not made any critical comparisons of this drug with other miotics, my impression is that it possesses no special virtues over 2-percent pilocarpine, and, furthermore, it often causes more blurring of vision than the latter.

The second group of miotics consists of the anticholinesterase drugs.

Physostigmine (eserine) is probably the best known of these, although neostigmine, a synthetic alkaloid, has practically identical qualitative actions so that the two drugs may be considered together. In addition to rapid and intense miosis, they often cause a severe accommodative spasm. After their use, the accommodation remains in a hyperexcitable state for many hours. Long continued use of eserine may cause a follicular conjunctivitis. I have not observed this with neostigmine.

Eserine has a tendency to take on a pink color due to oxidation. To delay this the pH should be adjusted to 4 to 5. Many patients complain of smarting following instillation. The irritating quality of this drug must be due to something intrinsic since the

degree of irritation usually bears a direct relation to the concentration irrespective of the pH. It is usually employed in 0.25- to 0.5-percent solutions. Neostigmine, which is much less irritating, is used in 3-percent or 5-percent solution.

Di-isopropyl fluorophosphate (D.F.P.) Leopold and Comroe,[17, 18] and McDonald[19] have determined the effects of this interesting compound on normal and glaucomatous eyes.

D.F.P. is a very powerful miotic and has many undoubted advantages. Its prolonged action obviates the necessity of frequent instillations, and sensitivity is extremely rare. However, the unpleasant symptoms from the strong cyclotonia preclude its use in many patients. Detachment of the retina[20] and activation of a quiescent uveitis[21] have been ascribed to it, although personally I have not encountered such complications.

In spite of its unpredictability, I have found it most successful in cases of glaucoma associated with aphakia and I believe it to be the drug of choice in these cases. This does not mean that all aphakic cases are successfully controlled by it since many factors are involved.

It is an interesting fact that the unpleasant symptoms of ciliary spasm and congestion of the eyeball frequently seen after D.F.P. instillation are usually absent or minimal in cases of aphakic glaucoma. Leopold and Comroe[17] have advanced a theory to account for the lack of ciliary spasm. They suggest that a lens with intact zonular fibers must be present for the pain of ciliary spasm to develop. However, this would not account for the lack of vasodilatation in these cases.

The following theory might explain the absence of both factors. The vitreous is known to be very rich in cholinesterase. Brückner[22] has shown that in certain animal eyes its concentration is four times greater in the vitreous than in the aqueous. Following cataract extraction, the barrier between the posterior chamber and the vitreous is

usually disrupted and the vitreous often bulges forward into the anterior chamber.

Thus, it is possible that, in aphakics, there is so much cholinesterase present in the aqueous that it is not all destroyed by the one drop of D.F.P. usually instilled. If so, the remainder might exert some control on the acetylcholine formation and thus the whole effect of D.F.P. would be tempered down with a consequent reduction of the unpleasant symptoms.

Tetraethyl pyrophosphate (T.E.P.) is a colorless liquid of low volatility which is the active ingredient of the insecticide hexaethyl tetraphosphate which was used in Germany during the recent war. T.E.P. is highly toxic and produces marked miosis in animals and man. Pharmacologic studies have shown that it is a very efficient inhibitor of cholinesterase, being more effective in this respect than either D.F.P. or eserine. It is even more unstable than D.F.P. and, like the latter, must be dispensed in peanut oil.

The miotic and antiglaucoma activity of T.E.P. has been investigated by Grant[23] of the Howe Laboratory of Ophthalmology. His studies indicate that in normal human eyes T.E.P., 0.1-percent solution in peanut oil, produces rapid miosis (in 7 minutes), spasm of accommodation, eye pain, and brow ache. The accommodation returns to normal after 4 days, but a relative miosis may persist for 2 to 3 weeks with a progressive relaxation as the days go by. In some of the eyes a slight transient engorgement of the conjunctival vessels occurs. There is no local discomfort at the time the drops are used, and slitlamp examination shows no evidence of damage to the corneal epithelium. In no instance have systemic symptoms been noted.

Grant has studied the effects of T.E.P. on 15 patients with chronic primary or secondary glaucoma. In most instances T.E.P. did not reduce the tension in eyes in which it could not be reduced by other miotics. There were 1 or 2 exceptions, but in general this was true.

II. EFFECT ON THE VASCULAR SUPPLY OF THE ANTERIOR SEGMENT OF THE EYE AND ON THE BLOOD-AQUEOUS BARRIER

It is well known that after the instillation of certain miotics the conjunctival and ciliary vessels may become engorged. This is characteristic of the derivatives of acetylcholine, such as mecholyl and carcholin, which cause it quickly, and even more characteristic of the anticholinesterase drugs, particularly D.F.P., in which the congestive action is delayed.

In the case of D.F.P., engorgement of the iris vessels may occur, as I have often observed by slitlamp examination. I have not noted this to the same degree with other miotics. This is sometimes accompanied by the appearance of cells in the aqueous when 0.2-percent solution is used. There is never any tendency to formation of posterior synechias. It is an interesting fact that these congestive features never appear until 10 to 24 hours after instillation of the drug. They can, of course, be eliminated by atropine which blocks the action of acetylcholine on the effector cell.

This delay in the appearance of the vasodilator effects is difficult to explain. Perhaps the accumulated acetylcholine cannot be absorbed by the tissues and thus causes vasodilation, first of the iris vessels, with the congestion gradually spreading to the anterior ciliary and the conjunctival vessels. All these congestive features usually disappear in 2 or 3 days as the eye becomes accustomed to the drug.

There is considerable evidence to prove that most miotics have a profound effect on the blood-aqueous barrier, and on the osmotic pressure of the aqueous.

Swan and Hart[24] showed that, in rabbits, instillations of mecholyl, carcholin, and eserine all caused a significant increase of the protein content of the aqueous. Pilocarpine did not. Studies with intravenous inulin, a large molecule polysaccharide, demonstrated that this substance, which does not ordinarily pass the blood-aqueous barrier

in rabbits, passed freely into the aqueous after instillations of eserine, carcholin, and mecholyl, but not after pilocarpine. Similar studies made with intravenous dyes such as sodium fluorescein showed that after eserine, carcholin, or mecholyl instillations, the dye appeared in the anterior chamber 4 to 8 minutes before it appeared in the control eye.

More recent experimental work by Leopold and Comroe,[18] by Scholz,[25] and by von Sallmann[26] indicates that D.F.P. also produces a marked change in capillary permeability to flourescein and a definite increase of protein in the aqueous. This change in the permeability of the blood-aqueous barrier is probably of marked significance in changes in the intraocular pressure.[27]

III. EFFECT ON INTRAOCULAR PRESSURE

It has long been felt that miosis is not the only factor which reduces the tension of the eyeball, since the miotic drugs have been known to accomplish this in cases in which the iris angle appears gonioscopically to be completely blocked by adhesions and even in cases of complete aniridia. Therefore, other possibilities must be considered.

The vasodilator effect which all miotics possess to a greater or less degree is probably a most important one. Because of this vasodilator factor intraocular pressure tends to rise slightly after instillation followed by a fall as the other factors become operative.

This was shown years ago by Wessely[28] who noted that eserine dropped into a rabbit's eye gave a marked dilatation of the vessels of the iris and ciliary body, also that the protein in the aqueous was increased and that entrance of intravenous fluorescein into the anterior chamber was facilitated. Eserine also caused an increased tension in rabbits a few minutes after the pupil had become miotic. This lasted 15 minutes, dropping back to normal and then becoming subnormal.

Clinically, we see certain cases of glaucoma in which the tension rises following the use of miotics and remains elevated. I have seen it occur once after eserine, 6 times

following D.F.P., and once with T.E.P. I have never seen it following pilocarpine. It has been reported rarely with carcholin and with mecholyl.

Let us consider the various possible factors which might tend either to reduce or increase the introcular pressure following the instillation of miotics.

ACTION OF MIOTICS

Factors tending to reduce tension	*Factors tending to increase tension*
1. Mechanical freeing of the angle.	1. Vasodilatation of iris and ciliary body with increase in their volume.
2. Contraction of longitudinal fibers of ciliary muscle on the scleral spur, opening up Schlemm's canal.	2. Cyclotonia causing lens to push iris root forward.
3. Reduction of blood flow to ciliary processes by ciliary spasm.	
4. Changes in permeability of blood aqueous barrier and the iris vessels.	

It can be seen that the action of miotics on the intraocular pressure is a complex one and represents a struggle between antagonistic forces. Sugar[29] has suggested the use of a vasoconstrictor drug, such as neosynephrin (1 percent), along with the miotic as a logical means of combating excessive vasodilatation and cyclotonia, and thus insuring a predominance of the pressure-reducing effects. He advises this only in shallow-angle glaucomas, and in acute congestive attacks, to reduce the chances of inadvertently raising the pressure.

In the six cases in which I have observed a rise of tension after D.F.P., and the one in which this occurred following T.E.P., all the eyes had very shallow chambers. I, therefore, have been following the advice of Sugar in all cases of shallow-chamber glaucoma whenever D.F.P. is used, and have used neosynephrin (1 percent) along with it.

Kronfeld,[20] a few years ago, attempted to correlate the responsiveness to miotics with the gonioscopic findings in various types of glaucoma. His conclusions were that:

1. In shallow-angle glaucoma, both in the

chronic and in the congestive phase, miotics were successful if not more than three-fourths of the angle was closed off by synechias.

2. In glaucoma associated with delayed reformation of the anterior chamber, miotics were often successful in reducing the pressure, provided the peripheral anterior synechias were filamentous in nature and not too solid.

3. In glaucoma associated with exfoliation of the lens capsule, miotics were notoriously inefficient.

In all other types of glaucoma no correlation was found.

In my own experience, very little correlation exists between the gonioscopic picture and the response to miotics in any type of glaucoma, the possible exception being that associated with exfoliation of the lens capsule. This type is seldom controlled by miotics. Even in the shallow-angle, iris-block type with few synechias, there are many cases that will not respond. In some patients both angles will look exactly the same, yet one eye will respond to miotics and the other will not. There are too many other factors beside the miosis to permit correlation.

What, then, is the value of miotics in the treatment of glaucoma?

1. Certainly in acute congestive attacks they are of inestimable value in bringing the tension under control before surgery is attempted.

2. In chronic simple glaucoma a few patients may be carried along successfully for years on miotics alone. I think this is rare, but perfectly possible, in both the shallow-angle and the wide-angle types, if treatment is instituted early.

3. They are often very helpful after operations which are only partially successful.

4. They are indicated after cyclodialysis as an aid in maintaining an open cleft.

Their danger lies in our placing too much reliance on them. Patients are apt to grow careless in using them and, therefore, should be frequently observed if on a miotic regime.

In most instances the beneficial effects of miotics are not sufficiently prolonged to postpone surgery indefinitely.

DISCUSSION

When all is said and done, an ophthalmologist's choice of a miotic is based on his own experience. Without wishing to appear too dogmatic I would like to state what my experience has been. In acute glaucoma I want to use a drug that will bring the tension under control quickly. For this I usually employ the synergistic combination of mecholyl (20 percent) and neostigmine (5 percent) every 15 minutes for an hour or two, until the tension comes down to normal, and surgery can be performed. Equally good results may be accomplished by similar use of a combination of pilocarpine (4 percent) and eserine (0.5 percent). I am a little fearful of D.F.P. in these acute congestive cases.

In chronic simple glaucoma I depend on pilocarpine (1-percent to 4-percent solution, 2 to 4 times daily) to control the pressure. If this is ineffective, I usually suggest operation and waste no more time with other miotics, particularly when the patient shows well-defined field changes.

There are exceptions of course. A patient on whom surgery is contraindicated for any reason, or one on whom surgery has been performed without complete success, deserves further trial with some other miotic. In these instances I may try the combination of pilocarpine and neostigmine, or D.F.P. (0.05 percent) solution. In using the latter I combine it with 1-percent neosynephrin in all cases with shallow angles.

I have found carcholin (1.5-percent suspension in anhydrous petrolatum) valuable in patients who develop sensitivity to other drugs.

In glaucoma associated with aphakia, I use D.F.P. (0.1 percent) solution as my first choice. I may use adrenalin borate (2 percent), particularly if the pupil appears blocked by vitreous.

In glaucoma secondary to uveitis I do not use miotics in active stages, but treat the

patient with atropine and adrenalin borate. However, in mild chronic cases with white eyes and no tendency to synechias, I often use pilocarpine. In old cases with the iris plastered to the lens, pilocarpine may be helpful. I am inclined to avoid strong vasodilating drugs in glaucoma secondary to uveitis.

In glaucoma associated with exfoliation of lens capsule, in hemorrhagic glaucoma, and in buphthalmos, I spend little or no time using miotics, but proceed to other measures.

CONCLUSIONS

1. In spite of an enormous amount of work done on the subject we are still not certain just how miotics lower the tension. Clinical experience and experimental work suggest a combination of miosis and an opening up of the blood aqueous barrier with changes in the osmotic relationship.

2. Some drugs produce more vasodilatation and cyclotonia than others, although their miotic effects may seem to be equal.

3. These vasodilatating and cyclotonic actions of miotics are probably of considerable importance in determining their effect on the intraocular pressure.

4. The combination of 1-percent neosynephrin with a miotic should be a rational procedure in glaucomatous eyes with shallow angles, especially when the miotic has strong vasodilating and cyclotonic actions.

5. Although we are learning more and more about the iris angle through gonioscopy, we are still not in a position to predict just what type of glaucoma will respond to miotics.

6. Generally speaking, miotics are valuable in early cases of both acute congestive and chronic simple glaucoma in bringing the tension under control while evaluating the patient for proper surgical procedure. They are also extremely helpful after operations which just miss being 100-percent successful. Although miotics alone may carry a few glaucoma patients along satisfactorily for years, they must be considered an adjunct to, rather than a substitute for, surgery.

NASAL CONTRACTION OF VISUAL FIELDS IN GLAUCOMA

Wiktor Arkin, M.D.

Warsaw, Poland

Some of the factors which may contribute to the pathologic processes in glaucoma have not, as yet, been satisfactorily elucidated. One of these factors is the nasal contraction of the visual field which is, in my opinion, one of the important signs of this disease.

CIRCULATION THEORY

In many monographs, this phenomenon is explained by the theory of Arlt and Rydel.[1] Their theory, which seems to have more probability than others, is based on the fact that circulation of the blood is poorer in the temporal parts of the retina, since the vessels that go out of the optic-nerve disc to this region have a longer course than those which run to the nasal part. The temporal vessels describe a long circle, while the nasal ones go straight to the periphery.

Moreover, it must be remembered that the disc (the exit of the vessels and nerve fibers) is situated eccentrically at the nasal side and not in the center of the retina.

Wegner[2] found, when producing experimental anemia of the retina (pressing the eye), that the nasal half of the visual field disappears first, and only later, the temporal half. I could not confirm this phenomenon either in others or in myself. The visual field darkened equally on both sides and, as the pressure increased, suddenly ended in total blindness.

Another weak point in the circulation theory is the fact that macular vision is preserved for a long time after peripheral vision is impaired. Since both the macula and periphery depend for their nutrition on the small vessels, it would seem logical to assume that, if pressure exerted on the vessels was the exclusive decisive factor, macular and peripheral vision would be equally impaired.

One explanation offered for this difference in the rapidity of visual impairment is that, in the region of the macula, the vessels are deeper and are, therefore, better protected against pressure. Yet, one must consider the observations of Jacobson and Gamo Pinto[3] who found that the greatest loss of visual field corresponded to the deepest cupping of the opposite side of the disc.

ARGUMENTS AGAINST THEORY

There are a number of arguments that can be presented in refutation of the theory of Arlt and Rydel.[1]

1. In arteriosclerosis, the visual fields, unlike those in glaucoma, show a uniform contraction, although, in this disease, there is also disturbance of the circulation of small blood vessels.

2. Tangent-screen studies of visual fields in glaucoma always demonstrate that the loss of the visual fields is in connection with the blindspot. This would seem to indicate that the pathologic condition first affects the nerve fibers. It would seem logical to assume that, if pressure on the vessels was primary, the peripheral parts of the retina would be affected since it is they which suffer first from a circulatory disturbance. In this case, contraction of the visual field would proceed from the periphery and would have no connection with the blindspot.

3. The presence of an annular scotoma coming directly from the blindspot would seem to indicate that there is direct pressure on the nerve fibers.

4. In arteriosclerosis, atrophy of the retina and secondary atrophy of the optic nerve make a hollow cup of the disc that is easily distinguished from glaucomatous cupping.

IMPAIRMENT OF NERVE FIBERS

Such arguments as have just been presented would tend to show that the contraction of the visual field is immediately connected with the impairment of the nerve fibers on the margin of the disc (and it is interesting to note in this connection that Arlt and Rydel[4] indicated that the temporal nerve fibers going out from the disc describe the same circle as the blood vessels).

HYDROSTATIC PRESSURE

APPEARANCE OF DISC

According to Fuchs,[5] excavation of the disc can be ascertained only by the curving of the vessels on the brim of the disc, because the nerve fibers are transparent and invisible.

However, if one studies the appearance of the disc during the period of already visible but not yet complete excavation, the cupping can be distinguished by the shadow cast by the overhanging brim. The disc itself has a grayish color, and the vessel trunk with all its capillaries is depressed on the nasal margin. Where the disc is not yet excavated, it has a rosy color.

Examination with the modern electric ophthalmoscope can also rule out the possibility that one margin of the disc is elevated. Such an examination gives the impression that the temporal portion is excavated to its edge, while in the nasal portion, the excavation does not reach the margin.

Fuchs[5] discussed this finding and acknowledged that even when cupping had taken place, nerve fibers remained on the nasal portion of the disc.

ANATOMY OF POSTERIOR REGION OF EYE

These facts would seem to establish the great probability that cupping of the disc begins on the temporal margin. In order to arrive at an explanation for this, it is necessary to have in mind the structure of the posterior region of the eye and particularly the course of the optic nerve and the place where it enters through the sclera.

The optic nerve enters the eye obliquely creating an acute angle with the nasal wall of the eye and an obtuse angle with the temporal part. This anatomic fact has significance in that it divides the internal pressure of the posterior wall of the eye.*

This pressure, which has a perpendicular direction, can be subdivided into two components: (1) that going along the nerve but not pressing on the nerve fibers (fig. 1A),

---

* It must be remarked that the interpretation herein presented depends upon the existence of a flow through the nerve. Really such a flow exists, although it is very slow. Therefore, the law of Dascel does not apply.

and (2) that going perpendicular to the nerve which presses the temporal nerve fibers against the margin of the disc (fig. 1B) and pushes the nasal nerve fibers away from the margin (fig. 1C). Physics teaches us that pressure in a curved pipe is greater on the convex than on the concave wall.

It can be justly remarked that, since the optic nerve is not a pipe, such an analogy cannot be made. This contradiction is, however, more apparent than real.

Fig. 1 (Arkin). Direction of the internal pressure of the posterior wall of the eye. (A) That going along the nerve but not pressing on the nerve fibers. (B) That going perpendicular to the nerve and pressing the temporal nerve fibers against the disc. (C) That pushing the nasal nerve fibers away from the margin.

CUPPING OF THE DISC

The disc, as is known, is not a flat surface but has a small hollow known as the physiologic excavation. The physiologic excavation does not reach the margin of the disc, but it is always distinctly marked, being sometimes even in the shape of a funnel.

Glaucomatous cupping of the disc is the consequence of the enlarging and depressing of the physiologic excavation. How often in doubtful cases of glaucoma, when other symptoms are not sufficiently evident, does one seek diligently for any alteration in the physiologic excavation.

When intraocular pressure is pathologically increased, the two components of that pressure already described press immediately and with a distinct difference on the lateral walls of the physiologic excavation.

As soon as the physiologic excavation becomes a pathologic one, the difference in these two components of the intraocular pressure, following the laws of hydrostatics, constantly increases.

ANATOMY OF THE OPTIC NERVE

One other factor must also be considered. When any portion of the optic nerve from the brim to some transversal section (fig. 2) is examined, it is seen that, because of the oblique course of the nerve, the length of

Fig. 2 (Arkin). A transversal section of the optic nerve shows that, because of the oblique course of the nerve, the length of the temporal part of the section is greater than the length of the nasal part.

Fig. 3 (Arkin). The bulk of the nerve is greater on its nasal side (after Fuchs).

the temporal part of the section is greater than the length of the nasal part. It follows, therefore, that the bulk of the nerve is greater on its nasal side (fig. 3).

Arlt and Rydel[6] and Fuchs[7] made casual mention of these observations but gave no proper explanation for them.

It is in keeping with the laws of hydrostatics to postulate that a difference in the extent of nerve-fiber accumulation would produce a difference in the degree of resistance of the eye walls. The temporal wall, with fewer nerve fibers, would yield more quickly to increased intraocular pressure and would also show greater excavation than

the nasal wall. An automobile tire under excessive pressure always blows out on the convex side.

ANATOMY OF THE VASCULAR TRUNK

When one considers that the vascular trunk with all of its principal vessels is at the nasal wall of the excavated disc, it would seem to contradict the theory of a different pressure and different resistance on the nasal and temporal sides of the disc. This contradiction is only apparent, not real.

Thus far, only the difference in pressure on the lateral sides has been explained. But the vascular trunk has a central position. None of the vessels except the small macular ones pass over the temporal margin of the disc. Rather, the majority pass over the nasal, superior, or inferior, brim of the disc. When the tissue of the nerve becomes atrophic and hollow, the trunk bends in this direction.

Another factor that must be explained is why, in some cases, there is a contraction of only one-fourth of the visual field (notching of the visual field—symptom of Ronné).

Proponents of the circulation theory attempt to explain this by saying that it is because there is only one artery—superior or inferior. The "hydrostatic" theory herein advanced explains it by saying that it is due to the difference in the resistance of the upper temporal and lower temporal margins of the disc caused by a difference in their structure. Some authors have reported a difference between the size of the superior and inferior walls of the excavation.[3]

Finally, it is necessary to explain why the macular vision remains intact longer than the peripheral. The shorter course of the vascular and nerve supplies of the macula and therefore its better nutrition would seem to retard the decay of the macular vision. The same phenomenon is observed in optic-nerve atrophy deriving from other causes.

CONCLUSION

I admit that the theory herein presented is only an attempt, as is the blood-circulation theory, to explain the nasal contraction of the visual field in glaucoma, and it by no means excludes the circulation theory.

However, the circulation theory explains *only one factor—that its poorer blood supply* put an additional burden on the temporal part of the retina.

The theory I am presenting takes into account not only the existence of a different hydrostatic pressure but also the existence of a different degree of resistance on the nasal and temporal sides of the disc. It would seem, therefore, that the circulation theory and my "hydrostatic" theory complete each other.

SUMMARY

The cause of nasal contraction of the visual field in glaucoma has never been satisfactorily explained. The best known theory is the blood-circulation theory.

I submit as additional considerations the oblique course of the optic nerve, which makes the length greater at the temporal part of the retina, and the consequent difference in the pressure acting on opposite sides of the physiologic or pathologic excavation, as well as the discrepancy in tissue resistance on the nasal and temporal margins of the disc.

CONGENITAL CATARACTS*

A SURVEY OF THE VARIOUS TYPES OF OPERATION

CECIL H. BAGLEY, M.D.

Baltimore, Maryland

There has always been some question as to the best method of removing congenital cataracts. To evaluate the various surgical procedures, we have studied the operations performed on 87 eyes with congenital cataracts. The operations were performed at the Wilmer Institute between October, 1943, and November, 1947, by the members of the full-time staff, the visiting staff, and the house staff. In all the cases the cataracts were present at birth or were noted shortly thereafter; the study includes both mature and immature cataracts. The average follow-up on the cases was 9.4 months. The longest period of observation was 4 years.

Similar statistical studies have been made by Horay,[1] Klare,[2] Kiss,[3] Chechik-Kunina,[4] Falls,[5] Owens and Hughes.[6] Owens and Hughes surveyed the operations on congenital cataracts performed at the Wilmer Institute between 1925 and October, 1943. Our data have been analyzed similarly to the method used by Owens and Hughes. This was done so that comparisons can be made of the results in the more recent years with the results in earlier years. The cases were analyzed to determine what effect the preoperative and operative factors had on (1) the final visual outcome, and (2) the occurrence of postoperative complications.

ASSOCIATED OCULAR DEFECTS

The first preoperative factor to be considered was the presence or absence of associated ocular defects. In 32 eyes (36.8 percent) the congenital cataracts were associated with other ocular defects, such as nystagmus, microphthalmos, strabismus, and congenital coloboma of the uveal tract. When strabismus was considered a congenital defect, the operation had been performed on the nonfixating eye.

Table 1 shows the occurrence of these various congenital defects in our group of cases. It was found that the presence of as-

sociated ocular defects was the most important factor in determining the final visual outcome.

Table 2 shows the relationship of the final vision to the presence or absence of associated ocular defects. Of 47 cases with no associated ocular defects in which the final vision was known, 70.2 percent obtained a final vision of 20/70 or better, while only 12.8 percent had a final vision of less than 20/200. On the other hand, in 13 cases with associated ocular defects in which the final vision was known, 30.8 percent obtained a final vision of 20/70 or better, while 38.4 percent obtained a final vision of 20/200 or less.

AGE AT OPERATION

One of the most controversial points in the treatment of congenital cataracts is the

TOTAL NUMBER OF OPERATIONS

Table 7-A shows that there was no significant relationship between the number of operations performed and the presence of associated ocular defects. Table 7-B is a similar study of the number of operations required when the cases are divided according to the age of the patient at the time of operation.

It shows that the age of the patient at time of operation had no significant effect upon the number of operations required to remove the congenital cataract satisfactorily.

The number of operations required to remove the congenital cataract completely in the various methods of operation are shown in Table 8. This table presents an interest-

ing contrast between the cases operated on by the method of linear extraction and those operated upon by the method of needling followed by a subsequent lavage.

Naturally in all the cases in which needling was followed by subsequent lavage, 2 or more operations were performed. However, in 50.0 percent of the cases in which a linear extraction was used only one operation was necessary.

The use of the linear extraction, therefore, reduces the total number of operative procedures necessary and thereby greatly decreases the anesthetic and operative risks. Table 8 shows that only one operation was required in 69.2 percent of the cases in which the method of single or repeated needlings was employed. However, when this method of operation was used, the final visual result was poorer than the results obtained after linear extraction or needling followed by subsequent lavage.

NUMBER OF DAYS IN HOSPITAL

Table 9-A shows there was no significant relationship between the number of hospital days per patient and the presence or absence of associated ocular defects. Table 9-B shows a similar lack of correlation between the age of the patient at time of operation and the total number of hospital days per patient.

However, Table 10 shows that the method of operation had an important relationship to the total number of hospital days per patient—64.3 percent operated upon by needling followed by subsequent lavage spent 14 or more days in the hospital, while only 35 percent operated upon by the method of linear extraction spent 14 or more days in the hospital. The method of linear extraction is therefore superior in this respect because it has significantly decreased the number of hospital days per patient.

COMMENT

A comparison of our results with those reported by Owens and Hughes is interest-

ing. In our cases the operations have been performed since October, 1943, while those reported by Owens and Hughes were performed before October, 1943. In the earlier series associated ocular defects occurred in 55.8 percent, but in our series similar associated ocular defects were present in only 36.8 percent, indicating that in the more recent years, operations have not been performed on many eyes having gross defects that would have been subjected to operation in the past.

In the early series, Owens and Hughes found better visual results when the operation was performed on patients over 2½ years of age. In the more recent series, the number of patients operated on at an early age is smaller. To obtain a large enough group to make a similar comparison, it was necessary to separate those cases operated upon when the patient was under 4 years of age from those operated upon when the patient was over 4 years of age. The comparison of the visual results of these groups confirmed the results of the early study by showing that the operative results were superior when the operation could be delayed.

The analysis of the operations performed since October, 1943, confirms the earlier experience that the method of single or repeated needlings does not give as good final visual results as linear extraction or needling followed by subsequent linear extraction.

From our data the most striking point in favor of the linear extraction is the reduction in the total number of operations necessary to remove the cataract completely. Owens and Hughes found similar results in their analysis. They reported that the percentage of cases requiring subsequent operations was essentially the same in the group having the single operation of linear extraction as in the group having the double operative procedure of discission followed by linear extraction.

In our series 50.0 percent of the cases having the single, primary operation of linear

extraction required only one operation to remove the cataract completely. The use of the simple linear extraction not only cuts down the total number of hospital days per patient, but greatly reduces the anesthetic and operative risks of removing congenital cataracts.

APHAKIA*

ALFRED COWAN, M.D.
Philadelphia, Pennsylvania

The purpose of this paper is to consider briefly and to stress again some of the salient features concerning the optical management of aphakia.

CHANGES IN APHAKIC EYE

The removal of the crystalline lens system changes the eye into an entirely different optical instrument. Using the constants of the normal, simplified schematic eye of Gullstrand, the power is reduced from 59.74 diopters to 43.08 diopters, a difference of about 16.6 diopters for air. This produces a principal point refraction of about 12.6 diopters of curvature hypermetropia.

The two principal points of the normal eye which were 1.505 mm. and 1.631 mm. behind the cornea now coincide at the vertex of the optical zone of the cornea. The nodal points which lay 7.13 mm. and 7.256 mm. behind the cornea in the lens containing eye are now replaced by a single point 7.8 mm. behind the cornea.

The direction of the visual axis, therefore, is changed and the eye must turn in a different direction to obtain an image at the fovea. The anterior principal focal distance is 23.214 mm. instead of 16.74 mm. in the normal eye. The size of the retinal image by the aphakic eye to that of the lens-containing eye is in the proportion of 23.21:16.74, about 1.38×. It would be formed 31.014 mm. behind the cornea, that is 7.014 mm. behind the retina of the aphakic eye; a refractive change of about 4 diopters for each 3 mm. of elongation instead of about 3 diopters for each 1-mm. difference in the normal eye, but the proportion of 4:3 does not hold precisely unless the correcting lens is placed at the anterior principal focus of the eye.

REFRACTION OF APHAKIC EYE

The lens that would correct this error and bring forward the image of a distant object so that it would be formed on the retina, must be of such dioptric power and denomination that the distant object would be placed (optically) at the far point of the eye which lies about 79.43 mm. behind the cornea. If this lens were situated at the anterior principal focus of the eye, it would have a power of about +9.75 diopters and the retinal image would be 38 percent larger

than the image in the normal eye. Of course, the spectacle lens is always set closer than 23 mm. from the cornea.

If it were placed at about 14 mm. in front of this schematic aphakic eye, it would have to have a power of about +10.7 diopters and, while the retinal image would not be so great because of the lessened distance, it would still be about one-third larger than that in the normal, lens-containing eye.

The size of the retinal image in aphakia depends on the refraction of the eye before removal of the lens. The image in the previously myopic eye will be larger than in the previously emmetropic eye because a convex lens of less power will be required to correct it. The image will be smaller in the eye that was hypermetropic before operation. But in every case of aphakia the retinal image is larger than before extraction of the crystalline lens and it is due to this enlargement that better than average normal visual acuity is frequently obtained in aphakia.

EYE DEVOID OF ACCOMMODATION

Besides these changes, the eye is now devoid of any accommodation whatever, and this loss is not unimportant because, even in aged persons, there is some power of accommodation, and be it ever so slight it helps in the adaptability of the eye. Properly corrected for distance and no accommodation, the vision becomes noticeably blurred from 4 meters in.

Also after removal of the crystalline lens, especially a senile lens, the eye becomes hundreds of times more sensitive to violet and ultraviolet light than before. Often there is some degree of erythropia after cataract operation, especially in those patients whose pupils have been enlarged by iridectomy. Cyanopia may occur immediately after extraction and last several weeks. These conditions are always transient.

In addition to the changes mentioned, regardless of the skill of the surgeon and the healthy success of an extraction of a senile cataract, there remains, in nearly every case, a more or less mutilated eye.

UNUSUAL NEW VISION

The wonder is why all of these elderly persons who have been operated on for cataract are not confused and, to a certain extent, disappointed in their entirely new kind of eye. It seems only reasonable that many find it hard to accustom themselves to it. The ophthalmologist, therefore, in treating a patient with aphakia after extraction of senile cataract, must always bear in mind that he is treating an elderly person who has just had his sight restored, but by the use of a strange, new optical instrument.

An unusual kind of vision is provided, possibly more acute than ever before, but with larger images, different aberrations, a changed pupil, and lessened focal depth. The patient must accustom himself to strong glasses with all their faults, a smaller field, and the probable image distortion with a newly acquired astigmatism.

Often it will be seen that the patient will find it difficult, at first, to fixate an object so that it will lie exactly on his new visual axis in order for it to be imaged at the fovea. While with most of these phenomena nothing can be done except to explain them away, some can be refined out or softened with carefully chosen and adjusted glasses. The optical management of aphakia is usually difficult for the younger man and often for the experienced ophthalmologist, too.

OPTICAL MANAGEMENT OF APHAKIA

All the accessory effects of the correcting glass before any ametropic eye are exaggerated in the case of aphakia corrected by a convex lens of around 10 diopters. The focal distances and the location of the lens itself are measured from its principal planes, and the position of the principal planes depends on the shape and thickness of the lens. Even though the finished lens has the same equivalent power, unless it is

of the same shape and thickness as the trial lens, the vertex power, and therefore the effectivity of the spectacle lens, will not be the same.

In low-power lenses, the difference in effectivity is so slight it may be disregarded, but in strong convex lenses it is important. For example, an 11-diopter, equal sided, biconvex lens 7-mm. thick has a vertex power of about 11.12 diopters. If this lens were replaced by a meniscus lens with—3-diopter back surface and +14-diopter front surface, and its back surface in the same plane, the effective power would be about 11.88 diopters—a difference of about 0.75 diopter. The same rate of change is also produced in the cylindric component.

IMPORTANCE OF VISUAL AXES

Uninformed opticians are under the impression that the pole of the spectacle lens (the so-called optical center) should coincide with the center of the pupil. With ordinary low-power lenses and normal eyes this may be done without notable error. But we know that, properly, the pole of the lens should coincide with the visual axis, which does not usually pass exactly through the center of the pupil.

In the case of displaced, mutilated, irregular, or multiple pupils the visual line may not go through the pupil at all. It may even pass through an opacity. In the case of a 10-diopter lens, in which a decentration of 1 mm. produces a prism of 1 diopter, proper centering in binocular aphakia is very important.

If the lenses are alike or nearly so, the conjugate movements of the eyes can bring them into such parts of the lenses that the apparent displacement and distortions are in the same direction for the two eyes; but if they are improperly adjusted with regard to the visual axes or if there is a material difference in the strength between the two lenses or if they contain strong cylinders with marked angular difference between

their axes, the prismatic effect is unequal as soon as the eyes turn from looking through the poles of the lenses. This prismatic effect, particularly in vertical and oblique directions, may be enough to cause the patient a great deal of discomfort.

TILTING OF LENSES

The tilting of these lenses is also important. Roughly about a 0.12-diopter cylinder is produced for every diopter of the given lens power with a tilting of 20 degrees, so that in looking at this obliquity through a 10-diopter lens there will be produced the equivalent of a 1.25-diopter cylinder with axis perpendicular to the direction of the movement of the eye. With a fixed spectacle glass, looking obliquely starts the moment the eye turns from looking straight forward. It is easy to conceive how, in looking obliquely through these lenses, a cylindric component at one time can be increased by a whole diopter while on looking along the opposite direction the same amount can be neutralized out.

AMOUNT OF REFRACTIVE ERROR

In the correction of any form of ametropia it is important first of all to determine the most nearly approximate refraction; but it is of equal importance that the finished spectacle lens produce as closely as possible the same effective power as that of the trial lenses. The refractionist therefore should give careful consideration to such controllable factors as the flexure of the lenses, the style of bifocal, and the best adjustment and position of the spectacles before the eyes. The importance increases, of course, with the amount of the refractive error.

In order to procure an effective power in the finished spectacle lenses which approximates that of the trial lens combination, the ophthalmologist whose equipment consists of old-fashioned double convex and double concave spheric trial lenses must either prescribe lenses that nearly duplicate the shape

of his trial lenses or the spectacle lenses must be carefully computed and ground with such back-front curves that they will have the same effectivity.

If the lens contains a cylinder, the closest duplicate of the double convex cylindric trial lens combination will have one side spheric and the other toric. For example, a +10D. sph. ⊃ +2.0D. cyl. ax. 180° should have one side a +5.0D. sph. and the other side a +5.0D. sph. ⊃ +2.0D. cyl. ax. 180°. But a double convex lens is not a good form even in a low power.

A good form lens of about 10 diopters is one which might be started from either about +14 diopters in front or about −3 diopters in back. Variations of 2 or 3 diopters in back-front combination will not make a great difference providing the back surface is concave.

At best the field is bound to be restricted through such a strong convex lens and all the faults besides the prismatic effects toward the periphery must be accepted. It is practically and theoretically impossible to eliminate the astigmatism of oblique pencils and other serious faults of a convex spectacle glass of around 10 diopters, especially if it contains a cylindric component.

APPROXIMATION OF EFFECTIVITY

An approximation of the effectivity can be obtained by arranging the lenses in the trial frame to resemble the shape of the finished lenses. Compared with the thickness and index of refraction of a biconvex lens of +10 diopters having an effective power of 10.08 diopters, two equal-sided lenses, +13 in front and −3 in back, will have an effective power of around +10.5; a +10-diopter meniscus with −3 back will have an effective power of +10.55 diopters.

Plano-trial lenses (every trial lens should have a plane surface) can be arranged so that they will conform to the finished spectacle lenses with negligible difference. Take a case, for example, in which by the ordinary

procedure of manifest refraction the final combination is +11 diopters.

Simply replace the single +11-diopter lens with two lenses, one −3 diopter with concave surface toward the eye as close to it as possible or at the exact distance the spectacle lens will be placed, and in front, in apposition to the plane surface of the concave lens, place the plane surface of a +14-diopter convex lens.

After testing subjectively for small differences with quarter- and half-diopter additions and subtractions, suppose the final result totals +10.5 diopters; order the lens ground with +13.5 diopters in front and −3 diopters in back.

The advantage of a meniscus over a flat lens is that, optically, it lies farther away from the eye than its actual position. This is good in hypermetropia because, for distance vision, the farther away from the eye the correcting lens the weaker its power must be and the larger the retinal image.

Suppose, for example, the result by the usual method is a sphero cylinder, +11D. sph. ⊃ +2.0D. cyl. ax. 180°. Ordinarily this combination will consist of a +11-diopter spheric lens in the rear cell and a +2-diopter cylinder in the front cell of the trial frame. Replace these lenses with a −2-diopter cyl. ax. 90°, concave surface toward the eye and as close as the spectacle lens will be and, in front of this with curved surface in front and plane surface behind and in apposition to the front, plane surface of the cylinder, a +13-diopter sphere.

In this way we have transposed the combination from +11D. sph. ⊃ +2.0D. cyl. ax. 180° to +13D. sph. ⊃ −2.0D. cyl. ax. 90°, its numerical equivalent.

This combination will, of course, not have the same back power and it will be necessary to add quarter or half diopters to both sphere and cylinder to find the difference. The axis, having been carefully determined in the first stage, will remain. If after the refinement by subjective tests

the final result is +12.5D. sph. ⊃ −2.0D. cyl. ax. 90°, order the lens to be ground as written. It is a good form.

By this procedure no computation is necessary nor need any allowances for shape or distance be made, provided the spectacle lenses are placed at the same distance from the eyes as were the trial lenses.

A change in distance of only 1 mm. away from the eye is likely to make a noticeable difference in effectivity in such strong lenses and this should be determined by pushing the lenses closer or pulling them away slightly when the patient returns to have them checked. If, by doing this, any improvement can be made one way or the other, have them readjusted.

PRESCRIBING BIFOCALS

These better forms can be obtained in fused bifocals in which the segments will be placed in the front spheric surface. If one-piece bifocals are preferred they can be ground with segment on the −3-diopter back surface in the case of spheric lenses. The spherocylindric lenses can also be made in one-piece bifocals but they must be specially ordered because the segment must be incorporated in the front spheric surface.

The advantages of cement bifocals should not be overlooked. Cement bifocals are optically good and will often be found useful and economical, especially for the first glasses when it is likely that the correction may have to be changed in a short while.

The segment of any of these bifocals should be so cut that the base is down, to neutralize somewhat, but more particularly not to exaggerate, the strong prism, base up, already in the lower part of the distance glass. For this reason flat-top segments are fundamentally wrong in any bifocal with convex distance lens.

Also, too often it is forgotten that the ordinary reading distance is nearer 14 inches (2.75D.) than 13 inches (3.0D.). If the media are clear and the visual acuity good, there is no reason ordinarily for stronger reading additions than 2.75 diopters. This will give a greater range and usually prove more satisfactory than additions of +3 or +3.25 diopters, which are so frequently prescribed in aphakic corrections. Stronger additions for near are justifiable, however, when the visual acuity is low, especially with monocular vision.

MONOCULAR APHAKIA

The correction of monocular aphakia (one eye normal with good visual acuity) is impractical, not only because of the diplopia due to the aniseikonia and to the prismatic effect of the difference between the glasses, but also because the patient has two different optical instruments, one dynamic with more or less active accommodation and normal adaptability and the other static.

It has been claimed that binocular single vision from infinity in to 10 inches has been obtained by the use of a contact glass for persons with monocular aphakia, even for young persons with accommodation in the normal eye sufficient for all ordinary distances.

If the retinal images are made equal in size it is possible to superimpose one on the other, but perfectly for only one distance at a time. But even then, mere equalization of the retinal images is not sufficient to produce single binocular vision. It is hard to conceive how this is physiologically possible with such a pair of eyes. But it is equally hard to explain accommodation for near vision in aphakia as has sometimes been reported.

The same reasoning regarding a contact glass can be applied to the usefulness of minifying glasses with the added disadvantages of their unsightliness and small field. While these devices may enable a patient to obtain a sort of binocular vision, it cannot possibly be good and might cause considerable discomfort, nevertheless if a patient seems to be comfortable with such a

quality of vision there is no reason why it should not be given.

In monocular aphakia, immature cataract in the other, the eye chosen for correction will, of course, be the one with the better visual acuity. In many instancs, however, the patient will prefer the use of the lens-containing eye even though the visual acuity cannot be brought up to that of the aphakic eye.

In monocular aphakia (only the aphakic eye functioning) the proper power and shape of glass and its position before the eye are important, but this is a simple matter compared with the correction of a pair of aphakic eyes.

CORRECTION OF BINOCULAR APHAKIA

It is in the correction of binocular aphakia that the greatest care must be taken to observe the characteristics of the eyes and to utilize the power, shape, and adjustment of the lenses to the best advantage of the patient. It is sometimes very difficult for an elderly person to coördinate two aphakic eyes, providing they do coördinate.

For this reason, probably in many instances the patient who submits to the removal of the cataract in the second eye is often disappointed after the second operation. This is especially true if there is a material difference between the refractions of the two eyes.

To the mind of the layman it is logical to suppose that two eyes are better than one, so much better that he is willing to risk a second operation even though a good result was obtained by the first. But it seems that most ophthalmologists also think the same way.

Often after combined operation, the amount of light which enters the eye through the enlarged pupil is so much greater than that to which the patient is accustomed that it causes considerable glare. This excessive light, particularly the selective nature of it, is likely to prove very annoying for some time following the operation, and protection is often desirable. For this purpose dark glasses may be given for those times when the occasion warrants. They should never be ordered for permanent, constant use. For obvious reasons light shades are just about useless. When dark glasses are given they should be dark enough to serve their purpose.

The provision of the best optical correction for aphakia requires special skill, experience, and a knowledge of the scientific principles involved, but also it must be constantly borne in mind, as already stated, that we have also to treat a patient that frequently is a more or less perplexed, elderly person who, by means of a serious operation, has just recently been given an entirely new kind of vision.

1930 Chestnut Street (3).

NEWER CONCEPTS IN THE CLASSIFICATION OF THE GLAUCOMAS[*]

H. SAUL SUGAR, M.D.

Detroit, Michigan

With the introduction of gonioscopic and chamber-angle depth observations into recent considerations of ocular hypertension, it has become obvious that many of the older ideas about glaucoma need modification. These changes have been sufficient to require a broader concept of the etiology, course, and even of the treatment of the various ocular conditions which have in common an elevation of intraocular pressure.

The term *glaucoma* does not apply to a particular ocular disease entity but rather denotes only the presence of increased intraocular pressure. Thus, glaucoma may be one of the manifestations of a large group of ocular diseases which may be called *the glaucomas*. From the viewpoint of what constitutes an increase in intraocular pressure and, therefore, glaucoma, it must be considered as that pressure which the individual eye cannot tolerate without some damage to its integrity.

Let us consider the classification of the glaucomas as a framework for the various concepts to be discussed.

Von Graefe[1] distinguished four clinical varieties of glaucoma; namely, acute glaucoma, absolute glaucoma, secondary glaucoma, and "amaurosis with excavation of the disc" (chronic simple glaucoma).

The classification in general use today is more elaborate but actually differs little from von Graefe's. It may be divided into three groups:

I. Primary or idiopathic glaucoma
   A. Congestive glaucoma (inflammatory, incompensated)
      1. Acute
      2. Chronic

   B. Chronic simple glaucoma (noninflammatory, compensated)
II. Secondary glaucoma
III. Hydrophthalmos

Absolute glaucoma is the end stage of any of the glaucomas and need not be included in any classification.

The weaknesses of this classification lie in the lack of etiologic connotation and in its failure to provide a cubbyhole for all the clinical varieties of glaucoma.

One of the things which started my dissatisfaction with this classification was my inability to classify properly the type of glaucoma which occasionally follows instillation of mydriatic drugs in patients with shallow anterior chambers and without previous ocular hypertension. Here the patient shows no evidence of vascular congestion, but the tonometric reading may be well over 60 mm. Hg (Schiøtz). The condition is acute but not congestive; so it does not fit into either the acute congestive glaucoma or the chronic noncongestive glaucoma cubbyholes, although the latter is where many men have placed it.

A review[2] of a series of 45 patients with acute glaucoma was made to determine whether the presence or absence of congestion was a justifiable criterion in the classification of glaucoma. The results of the study indicated that 95.4 percent of the 24 cases precipitated by mydriasis (mydriatic drugs or darkness-dilatation) were free from congestion at the onset. Of the 7 with acute episodes precipitated by accommodative effort, 80 percent started without congestion. In the group of 18 cases precipitated by vascular engorgement, presumably involving the vessels of the ciliary body, 53.3 percent were congested from the onset.

It appeared, then, that in a majority of cases of acute glaucoma, the onset was not

associated with congestion, but, after a varying period of time, the eye suddenly became congested, due, probably, to the presence of histaminelike metabolic products resulting from the poor nutrition and hypoxia associated with the interference with the blood supply by the high intraocular pressure.

Congestion is only a phase into which an eye with acute glaucoma may or may not enter, depending on the precipitating factors and the duration and height of the increased intraocular pressure. Therefore, the descriptive terms congestive and noncongestive and their synonyms were eliminated from the diagnosis and only appended after it as follows:

Acute glaucoma, noncongestive phase
Acute glaucoma, congestive phase
Simple glaucoma, noncongestive phase
Simple glaucoma, congestive phase

Another weakness in the generally used classification is its tendency to give the impression that the various primary glaucomas are various stages of the same disease so that one clinical picture may change to another and then even revert back to the original type. Beginning with Raeder,[3] in 1923, there has come a separation of the two primary glaucomas of adult life into two separate entities, based on the depth of the chamber angle. This has been amply confirmed by gonioscopic evidence and by provocative mydriasis.[2]

One confusing consideration is how to classify acute glaucoma which remains unrelieved by treatment. This is still acute glaucoma which has entered a chronic phase. The term acute glaucoma is used to designate a specific entity and should be used as the diagnostic term, even though the words "chronic phase" may be appended.

The classification which I wish to present is based on an attempt to continue the time-honored terms *primary* and *secondary* glaucoma and yet maintain an etiologic viewpoint.

My first attempts at classification of the glaucomas considered only chronic simple glaucoma as primary since this was considered the only condition whose relation to any other ocular disease was not known. Since acute glaucoma results from a known anatomic cause, it was classified as secondary.

Following this classification it was only a step further to avoid the terms primary and secondary entirely and simply to classify each type of glaucoma according to its causal relationships. But because we do not yet know the cause of the most important glaucoma—chronic simple glaucoma—and because of usage, I have reverted in teaching to the use of the terms primary and secondary.

The primary glaucomas, according to my present concept, are those which do not follow other ocular disease. In this group are included the idiopathic chronic simple glaucoma cases and those cases caused by anatomic and developmental anomalies. The latter are subdivided into the congenital glaucomas and acute (narrow-angle) glaucoma which depends on both an anatomic predisposition[4]—a narrow angle usually associated with high hyperopia—and the normal continuous growth of the lens with increasing age, together with such physiologic angle-narrowing factors as accommodation, dilatation of the pupil, and congestion of the ciliary body.

The classification of the glaucomas in Table 1 is suggested on the basis of the definition of primary glaucomas just presented.

A consideration of the diagnostic clinical features of each of the glaucomas would be beyond the space available in this paper. However, a consideration of the important ones, especially those which present a diagnostic problem and those about which newer concepts have arisen, will serve to describe the desired material.

GLAUCOMA SIMPLEX

By far the most important of the glaucomas is the classical glaucoma simplex. The usual patient with early glaucoma simplex has no symptoms until changes in the visual fields bring the condition to his attention. Occasionally some fogginess of vision and

TABLE 1

A CLASSIFICATION OF THE GLAUCOMAS

I. PRIMARY GLAUCOMAS

A. Chronic simple (normal angle width) glaucoma { noncongestive phase / congestive phase (rare)

B. Glaucomas caused by anatomic and developmental anomalies
  1. Congenital glaucomas
    (a) Hydrophthalmia
    (b) Glaucomas associated with aniridia or with neurofibromatosis
  2. Juvenile glaucoma. (Only those cases related to developmental anomalies belong here.)
  3. Acute (narrow-angle) glaucoma—due to anatomic plus physiologic angle-narrowing factors which lead to mechanical obstruction of trabecular spaces by iris. This includes the acute glaucoma associated with microcornea
    (a) Noncongestive phase—including "dilatation glaucoma"
    (b) Congestive phase—classical "acute congestive glaucoma" and the recurrent form called "chronic congestive glaucoma" in the older classification

II. SECONDARY GLAUCOMAS (Each may be subdivided into a noncongestive and a congestive phase; some never enter the congestive phase.)
  A. Secondary glaucoma due to mechanical blockage of the trabecular spaces
    1. Obstruction by iris
      (a) Acute secondary glaucoma due to lenticular intumescence
      (b) Acute secondary glaucoma due to dislocation of the lens into the anterior chamber
      (c) Glaucoma following operation for cataract—*aphakic obstructive* glaucoma—due to delayed reformation of the anterior chamber
      (d) Glaucoma associated with essential progressive atrophy of the iris
      (e) Glaucoma associated with retrolental fibroplasia
    2. Obstruction of the trabecular spaces by particulate matter
      (a) Glaucoma capsulare
      (b) Pigmentary glaucoma
      (c) Glaucoma due to obstruction by lens particles
      (d) Glaucoma due to tumor growth
      (e) Glaucoma due to cellular debris associated with active or healed iridocyclitis
  B. Secondary glaucomas due to lack of communication between the anterior and posterior chambers
    1. Secondary glaucoma due to seclusion of the pupil
    2. Secondary glaucoma due to total posterior synechia
  C. Secondary glaucomas probably due to overproduction of aqueous as a result of irritation of the ciliary processes
    1. Glaucoma associated with posterior dislocation of the lens so that latter touches ciliary processes
    2. Cyclitis and anterior choroiditis
  D. Secondary glaucomas due to obstruction of venous drainage
    1. Experimental and clinical glaucoma due to vortex-vein obstruction
    2. Secondary glaucoma in pulsating exophthalmos
  E. Secondary glaucomas due to newly proliferated anastomotic vessels involving the Schlemm's canal mechanism in rubeosis iridis (diabetic and arteriosclerotic) and following occlusion of the central retinal vein
  F. Secondary glaucoma resulting from trauma
  G. Secondary glaucoma associated with epidemic dropsy
  H. Secondary glaucoma associated with choroidal angiomatosis

diminished accommodation bring him to the oculist. Less frequently, colored halos around lights and headache are complained of. In the later stages the patient complains of night blindness, contraction of the visual fields, or even interference with macular vision.

Objectively, the ocular findings in simple glaucoma depend on the stage of the disease. The earliest findings are a slight ocular hypertension and changes in the pericecal visual field, usually manifested as a vertical increase in the size of the blindspot. As the

disease progresses, the field changes increase slowly so that various characteristic changes, such as Bjerrum's sign and Roenne's step, occur. Excavation of the optic disc begins at the temporal side of the disc. As the disease progresses, the excavation of the disc increases concurrently with contraction of the field, until only a central zone about 10 degrees in diameter remains.

If allowed to continue untreated, the tension usually remains between 30 and 45 mm. Hg (Schiøtz); and the central field is finally lost. In this state of absolute glaucoma, the

eye may remain painless and pale or may, rarely, after a considerable time, suddenly enter a congestive state, in which the conjunctival vessels become injected, the eye painful, and the tension high. In fact, the suddenness of the onset and the symptoms may be the same as in an eye with acute glaucoma which has entered the congestive phase.

The few eyes with early simple glaucoma which have been studied in the laboratory show no abnormalities. The late stages of unoperated simple glaucoma show only the effects of increased intraocular pressure.

The diagnosis of early simple glaucoma depends on routine tonometric studies. Tactile tension estimations are so notoriously inaccurate that they cannot be termed a useful subsitute for the instrumental measurements.

The experience of the residents in ophthalmology at the Detroit Receiving Hospital serves to emphasize the value of routine tonometry. In March, 1947, when the present glaucoma clinic at that institution was started, there were about 18 active glaucoma patients, all in an advanced stage. Routine tonometry on all eye-clinic patients of 40 years of age or over led to an increase of glaucoma patients during the first nine months to 118, a high proportion of which were in the earliest stages.

Gonioscopically, the chamber angle is normal in depth in simple glaucoma, although one occasionally finds cases of simple glaucoma in which the chamber and the angle are relatively shallow. The shallowness is coincidental, since the factors leading to relative shallowing of the chamber are present in persons of the age group affected. In the late stage of simple glaucoma in which sometimes a congestive phase appears, peripheral anterior synechias may form.

The slitlamp findings in simple glaucoma are entirely negative except in the later stages when congestive episodes may have occurred. Then the evidences of congestive and atrophic changes are seen.

The provocative tests, including the water test and pressor-congestion test,[7] are of considerable help in the diagnosis of early cases of simple glaucoma, especially when the tonometric readings are 28 to 30 mm. Hg (Schiøtz) or when the tonometric readings are lower but the history or clinical findings are suspicious. The provocative tests are significant only when positive.

In the more advanced stages, the diagnosis is made on the basis of the visual fields, the tension, and the appearance of the nerve-head.

PRIMARY ACUTE GLAUCOMA

The second of the glaucomas in importance is primary acute (narrow-angle) glaucoma. It is not difficult to diagnose in the full-blown congestive phase but the differentiation, in the noncongestive phase, from simple glaucoma and, in the congestive phase, from the secondary glaucomas, is usually difficult, and of much more than academic importance.

The actual onset of the noncongestive phase of acute glaucoma is hardly noticed by the patient. Blurring of vision may be noticed, especially among the younger patients. Sometimes the onset is associated with colored halos, or slight pain in the head or in the eye. These mild symptoms usually last a half-hour to two or three hours and then subside entirely, only to recur at varying intervals, becoming more frequent and lasting longer as time goes on, each attack leaving the anatomic conditions more favorable for further attacks. The circumcorneal injection associated with these episodes is slight, if any.

Occasionally the patient finds relief from his symptoms by the use of hot or cold applications, by looking at a bright light for several minutes, or by sleep.

Ultimately, one of the mild episodes will persist longer than usual, and suddenly the patient will experience marked diminution in vision, photopsia, swelling and redness of the conjunctiva, and pain in the head and the eyes, often so severe as to cause nausea and vomiting.

The sudden change in symptoms often

awakens the patient from sleep and occurs without any precipitating factor, it being an aggravation of the previous mild symptoms. It is induced by a sudden congestion of the globe, probably as a result of the accumulation of tissue metabolites within the eye when the blood supply and drainage of the intraocular fluid is impeded due to the high intraocular pressure. At any rate, the sudden aggravation of symptoms is attributable to the combination of high intraocular pressure and increased permeability of the vascular walls.

In some cases, the first mild noncongestive episode of acute glaucoma is followed by the congestive phase. Of course, if treated early with miotics, even the congestive phase subsides rapidly, and if the patient does not use miotics as a prophylactic measure it will likely recur, the disease passing again through the noncongestive phase. What has been previously called the prodromal stage of acute glaucoma is in reality the noncongestive phase of the disease.

In many patients with episodes of primary acute glaucoma, there is a history of onset of the condition following nervous shock. Many authors for this reason attribute primary acute glaucoma to a nervous cause. Actually the neurovascular factors are important only as the precipitants of the angle-blocking mechanism.

Objectively, the tension may not be different in the noncongestive and in the congestive phase. It is usually very high in the latter, since the additional vascular congestion adds to the mechanical obstruction of the angle.

. Shallowness of the anterior chamber is typical of this type of glaucoma and is its predisposing anatomic cause. For this reason the nonglaucomatous fellow eye of a patient who has had an episode of primary acute glaucoma may be classified as preacute glaucoma. The same term may be used to describe the interim of normality between episodes of primary acute glaucoma in either the noncongestive or the congestive phase.

Shallowness of the anterior chamber in this form of glaucoma is usually associated with high or relatively high hyperopia, especially during the patient's early adult life.

When vascular decompensation occurs, it produces not only chemosis of the conjunctiva but edema of all the ocular tissues. The corneal epithelium is so involved that details in the fundus are obscured. Blebs and vesicles appear on the cornea. The cornea loses its sensitivity. In the noncongestive stage, even in the presence of very high tension, the cornea is not edematous, and arterial pulsation is easily seen in the fundus.

The pupil is dilated in both phases of acute glaucoma but is irregular in the congestive phase. The dilatation, when it is not in itself the actual etiologic factor in the onset of the disease, is probably due to slight stretching of the eyeball and to the pressure effect on the nerves.

In rabbits, if a needle is inserted into the anterior chamber and the pressure increased, the pupil dilates, and it contracts when the pressure is decreased.

Barkan[8] suggested that the vertically oval shape of the pupil is due to anatomic narrowness of the angle above. Undoubtedly, in the congestive phase the blood supply to a few of the nerve fibers to the sphincter is affected irregularly, and irregularity of the pupil results.

The iris in the congestive phase becomes muddy and discolored. Some of the iris vessels become visibly distended. If the congestive phase persists any length of time, fine posterior synechias may form.

The nervehead in the noncongestive phase is normal. In the congestive phase, it is red but not excavated. If repeated attacks occur or if an attack persists, the disc becames rather rapidly excavated.

Biomicroscopy reveals abnormalities only in the congestive phase or after the eye has suffered the effects of long-standing pressure as in simple glaucoma. Edema of the epithelium, blebs, and vesicles are seen in the congestive phase. The contents of the anterior chamber and the vessels of the iris are difficult to see clearly in this phase. Chemi-

cal studies are of no etiologic significance but show only the results of the vascular changes.

In the noncongestive phase, gonioscopy reveals the contact between the iris and the trabecular wall. In the congestive phase, closure of the angle must be presumed, since the cornea is usually too cloudy for visibility.

In a person in whom a congestive attack is relieved spontaneously or with miotics, floating particles of pigment, irregularity of the pupil, occasional fine posterior synechias, and pigment on the posterior corneal surface are seen. Slight persistent pericorneal injection may be present. If a patient is seen for the first time after such an attack, the tension in the eye is usually below normal and an erroneous diagnosis of acute iritis may be made.

When the congestive phase of acute glaucoma has been allowed to exist without treatment, the eye eventually becomes blind and enters the stage common to all glaucomas, namely, absolute glaucoma. The eye remains injected, the episcleral veins remain dilated, vesicles form on the cornea, and the iris remains muddy. Pain persists. Gradually, the vascular system adjusts itself somewhat, and the eye often becomes less painful.

SECONDARY GLAUCOMAS

Of the secondary glaucomas, those due to obstruction of the trabecular spaces by iris deserve consideration as a group. They have the same mechanism as primary acute glaucoma. This is most obvious in the acute secondary glaucoma due to lenticular intumescence which not only has the same mechanism but has the same clinical picture except that only one eye is usually involved in the process; that any refractive error, even high myopia, may have been present; and that an intumescent cataract is present. An anterior chamber of normal depth in the fellow eye is an important differential sign. I have never seen a primary acute glaucoma with a normally deep anterior chamber in the fellow eye.

Secondary glaucoma following cataract operation has been proved clinically to be due to obstruction of the trabecular spaces by iris only since my preliminary report on the gonioscopic findings in 1940. It is important not only as proof for the fact that obstruction of the trabecular spaces can cause a rise in the intraocular pressure in human beings, but in the differential diagnosis from other glaucomas occurring coincidentally in an eye which has had surgery for cataract.

In this type of glaucoma, the obstruction of the trabecular spaces usually results from delayed reformation of the anterior chamber due usually to failure to obtain tight wound closure.

The clinical picture varies considerably, depending on whether it occurs early or late after the operation. When it occurs early, the eye is usually congested and painful, and may be mistaken for a postoperative inflammatory process. Late onset may be free of congestion and lead to symptom-free loss of vision as in glaucoma simplex.

The diagnosis depends on gonioscopy. The etiologic factor may be relieved surgically by the cyclodialysis operation in both the congestive and the noncongestive phases.

The secondary glaucomas due to obstruction of the trabecular spaces by particulate matter are of several types, depending on the obstructing material. The diagnosis in each depends on gonioscopic examination of the chamber angle. The type, designated as glaucoma capsulare,[9] is associated with the exfoliation of the zonular lamella of the lens capsule. It is impossible, in this group, to be certain whether the capsular debris or the pigment granules deposited in the trabecular spaces, or both, are the cause for this type of glaucoma.

A second type of secondary glaucoma associated with a marked deposition of pigment in the trabecular spaces, without capsular exfoliation, is a form of glaucoma which has recently been described as an entity. It has been designated as *pigmentary glaucoma.*[10]

It was observed in two young myopic individuals with degeneration of the pigment epithelium of the iris and ciliary body. The pigment was deposited as a dense trabecular pigment ring in the trabecular spaces and as Krukenberg spindles on the posterior cor-

diagnosis is more probably correct. In this case, the treatment is exactly the same as that for simple glaucoma, both medically and surgically.

The secondary glaucoma associated with cyclitis or anterior choroiditis is probably
Fig. 1 (Sugar). Graphic representation of the effect of cycloplegics and miotics in the treatment of cyclitic secondary glaucoma.

neal surface as well as on the anterior iris surface. It differs from chronic simple glaucoma clinically in its response to mydriasis by significant elevation of the intraocular pressure.

Secondary glaucoma due to obstruction by cellular debris in the angle is difficult to differentiate from simple glaucoma when the antecedent iridocyclitis is completely inactive. Only the history of a previous iridocyclitis and the gonioscopic and biomicroscopic findings suggest the possible cause. If the condition is and remains unilateral, the

due to an overproduction of aqueous and is usually temporary, lasting only as long as the irritative inflammatory process persists in a relatively quiet form.

It is interesting that early in these inflammatory processes, when the eye is congested, the intraocular pressure is usually lower than normal, as in ordinary acute iritis. This is presumably due to a general vasodilation involving the iris and ciliary body.

As the inflammatory process appears to subside, and the eye becomes relatively paler or completely white, the intraocular pres-

sure rises. Deposits on the posterior corneal surface increase, even though evidence of increased protein in the aqueous may decrease or even be biomicroscopically absent.

The diagnosis is important in that the intraocular pressure responds favorably to atropine or scopolamine and not usually to miotics, as the following case shows.

Case report. S. V., a 25-year-old man, was first seen by me on December 31, 1943. He had been entirely well until July, 1943, when he began to notice fogginess of vision, first in the left eye and later in both eyes.

Examination revealed a bilateral chronic granulomatous iridocyclitis. The visual acuity was: R.E., 20/30; L.E., 20/20. The tonometric readings were: R.E., 21 mm. Hg (Schiøtz) ; L.E., 60 mm. Hg. Both eyes were rather pale. Atropine (1 percent) was instilled into the left conjunctival sac three times daily. The response to cycloplegics was favorable, to eserine unfavorable as shown in Figure 1. The tension stayed normal from February 3, 1944, until a recurrence of the iridocyclitis appeared in June, 1946. This episode responded to scopolamine.

One other secondary glaucoma will be considered since some new thoughts concerning it have appeared. This is the secondary glaucoma associated with rubeosis iridis and following occlusion of the central retinal vein.

From the viewpoint of mechanism both of these are exactly the same.[11] The chamber angle early is open and shows the same newly formed vessels lining the angle and penetrating the angle wall. Later the angle becomes blocked by adhesion between the iris root and the trabecular wall.

The earliest case of this type I have seen was in a patient with one blind, painful, glaucomatous eye with diabetic rubeosis iridis, in whose other eye very localized small areas of rubeosis became evident near the pupil border and in a portion of the angle as the tension rose in that eye to 36 mm. Hg (Schiøtz). The angle was entirely open. The newly formed vessels lining the small areas of the angle could be seen penetrating

the trabecular wall, presumably to anastomose with Schlemm's canal.

The occurrence of this condition in an eye with poor nutrition and hypoxia, as a result of severe vascular disease, suggests a causal relationship. The formation of newly formed vessels is stimulated, causing anastomoses with Schlemm's canal and in some way destroying its usefulness.

The treatment of this form of glaucoma is cyclodiathermy for the pain, or enucleation. The presence of the newly formed vessels may lead to spontaneous hemorrhages (hence the term hemorrhagic glaucoma). When surgical treatment is attempted, these vessels nearly always preclude success. I have recently seen a case of hemorrhagic glaucoma associated with rubeosis in a diabetic girl, aged 23 years. I know of no other such case in so young an individual.

Occasionally one finds a combination of two forms of glaucoma in the same patient. This has been described as mixed glaucoma.[11] Mixed primary acute glaucoma and glaucoma capsulare occur. Simple glaucoma and secondary glaucoma following central vein occlusion have appeared together. There may even appear a superimposition of primary acute glaucoma coincidentally on the background of a simple glaucoma.

Summary

A new classification of the glaucomas based on clinical evidence is suggested. The classification is arranged so as to include the same groupings into primary and secondary glaucoma which usage has made universal.

The diagnostic features of those forms of glaucoma where newer concepts have appeared are presented.

Emphasis is placed on routine tonometry in all patients 40 years of age or over to make early diagnosis of glaucoma simplex possible, since it is the most important ocular disease in relation to blindness, and one whose ravages can be prevented to a large extent by early recognition.

SIGHT RESTORATION IN A SCHOOL FOR THE BLIND*

PURMAN DORMAN, M.D.
Seattle, Washington

Restoration or improvement of diminished vision is a different problem today from the one it was formerly. As is true in many other fields, conditions change. The diagnoses of pathologic conditions of the eye may remain the same, but the number of children within the various age groups who have eye afflictions is changing, thankfully, for the better.

As a marked example of percentage changes, the new cases entering schools for the blind approximated 3 percent last year due to gonorrheal ophthalmia neonatorum; whereas, 6 percent of new cases of this condition were noted in 1941; but contrast that with 28 percent in 1907! Other eye conditions will not respond with such remarkable speed, although a review of the eye records of pupils in schools for the blind throughout the country allows us to gain an excellent grasp of the many causes that now produce diminished vision.

I am indebted to the Committee on Statistics of the Blind for the information that the total number of pupils in schools and classes for the blind in America is 5,400. Of these, the records of about 3,700 children were studied for the school year 1945-46 when it was found that approximately 15 percent of the children are now blind because of cataracts which are largely of prenatal origin.

Discussion of sight restoration should include all phases of the handicapped individual's life and should not be limited to corrective eye treatment of pupils already enrolled in schools for the blind. It may be well to consider the subject under three categories: (1) prenatal care, (2) actual visual improvement, and (3) psychologic adjustment.

PRENATAL SIGHT RESTORATION

This grouping may be challenged by saying that it is a preventive classification but for the individual the end result by any name is the desired objective. The youngster who may have vision "restored" by an operation

of any form, or by any sort of medical treatment is no more fortunate than the youngster who did not lose vision because his parents did not transmit the visual fault that is considered as a "prenatal" cause.

Those prenatal causes, such as syphilis or the acute eye infections known as ophthalmia neonatorum transmitted from the birth canal, have decreased nearly 40 percent and 25 percent, respectively, within the past 10 years. Such advances are due partly to the greater vigilance of the health officers and partly to the general education that is definitely and steadily being absorbed by all parents, by workers for the blind, by teachers, and by the general public.

It is important that this educational process be continued ceaselessly by varied means. Only by general education has it been possible to pass state or federal laws that emphasize maternal and infant care. Not only should we strive to have more babies live but also to have more babies see.

Medical research now helps by considering in a special category the congenital cataracts of babies born from mothers who had German measles during the early months of their pregnancy. Only since 1941, when a severe epidemic of rubella in Australia infected many expectant mothers with the result that their children showed a greater frequency of these congenital cataracts, has the entire condition been considered a separate entity.

The suggestion has been made that, in order to prevent such congenital malformations in the future, the prospective bride be required to indicate on application for a marriage license whether she has had German measles, just as, at the present in some states, it is required to have a physical examination for syphilis.

Restoration of sight should unquestionably include study of the prenatal causes of blindness. To add to the knowledge of what caused the blindness and how it might have been prevented is the biggest job of all and the one that gives the greatest amount of satisfaction.

IMPROVING VISION

The second division, that of actual visual improvement, would be an oft repeated story, were the operations to be listed, what they were, why they were done, and on whom.

The school for the blind in the state of Washington, for which I am the admissions consultant, had a survey and a thorough review, in 1942, by the American Foundation for the Blind. As a result of this examination of everything that pertained to the school, with the exception of the finances, many changes were made.

Several children were operated upon for cataracts or for other conditions to improve their vision. Some have been improved sufficiently to be removed from the school. However, the greatest improvement was gained by a number of children as a result of having been better fitted with glasses because of more frequent examinations or because special lenses, such as telescopic magnifiers, have been prescribed.

The survey not only opened the eyes of some of our youngsters but our eyes as well. It stimulated us to look around at other schools for the blind and showed that other schools had similar weak points. For example, it was found in our school, as well as in others, that some children were admitted without a preliminary or previous eye examination. Sometimes children did not have eye examinations yearly, or did not have more frequent eye examinations when progressive eye conditions, such as high myopia, were noted.

Today, all children whose parents desire that they be admitted to the school for the blind are examined by an eye physician before the child is admitted to the school. In addition, the entrance eye examination reports are passed upon by the admissions consultant who is also the consultant ophthalmologist of the Blind Division, Department Public Welfare (incidentally a Board certificated man), who may deny entrance to any prospective youngster who is not blind.

All children are again examined by the

school ophthalmologist shortly after their entrance and again routinely yearly, even including those who have no eyes at all.

RETURNING SIGHTED CHILDREN TO THEIR HOMES

After review of our own past mistakes and our attempted corrections, we noted not only the faults relating to the medical needs but we perceived a weakness in our program covering the educational needs of the blind as well as the partially seeing child. We found our school well equipped and well developed for educational instruction along tactual methods. But the partially seeing pupils too often had been placed in the same classes as the blind, without regard to the better or more recent educational procedures or without regard to the utilization of visual media now available.

In spite of the acceptance of these partially seeing children, special educational facilities had not been provided. The partially seeing child had not had sufficient lighting for his greatly reduced eyesight. There had been an erroneous conclusion that the educational needs of the partially seeing and the blind were sometimes similar, sometimes identical—a conclusion manifested by certain types of vocational training that had been given to partially seeing students of the high-school age groups.

We found several children included in the school for the blind who had practically normal vision at the time of the independent, disinterested survey. Some eyes showed no reduction of vision, no intraocular or extraocular pathologic condition. The reasons for admittance of these children were: they were home-problem children; there was a mistaken recommendation made—sometimes by an optometrist and sometimes by a general practitioner; there was a broken home; or there was a suspected willful blindness in the child because a relative was blind, sometimes from some remote cause.

The attendance of these children at the school for the blind was easily remedied. What was not easily changed were the emotions, the attitudes, the living habits, the acceptance of the highly protective environment of the school, and the confusion that goes with returning these youngsters to their homes, sometimes against the will of their parents. This emotional shock of learning a second time that they are not wanted undoubtedly will have certain mental repercussions later.

A remarkable utilization of community resources was achieved when partially seeing as well as blind children participated in several play ventures with normal neighborhood children. Such activities included hikes, "wienie" roasts, and other youthful encounters dear to children everywhere. It was necessary for the superintendent of the school to initiate some of these activities, but after she realized that there had been isolation from neighborhood children, such problems ceased to exist.

Some children had been accepted by the school before a complete examination had been made by a competent ophthalmologist, before any corrective treatment had been attempted. It was obvious that the school accepted responsibility for which it was not prepared, and also that competent medical and adequate educational treatment had been delayed.

Our study revealed certain possibilities of improvement of the sight of the visually handicapped child by surgery, glasses, or some form of medical treatment. We endeavored to gain closer coöperation with our competent, associated eye physician so that whatever remaining vision the child had was maintained, safeguarded, and protected. But, what was more important to the youngster, he had more efficient use of his small amount of vision.

Two children, whose vision was improved from 2/200 to 10/200 by eye surgery undertaken after the survey showed the possibilities for such improvement, believed they should no longer read Braille, that they were not "blind children"—as indeed they weren't! They believed their better vision was adequate for all visual tasks of a seeing

person. Such visual improvement was not great as measured by our standards, but was sufficient for them to obtain an entirely new outlook on life, a new vision and acceptance of work, far beyond their previous abilities. Life for them was not blind, life was seeing.

In addition to the medical or surgical treatments, a re-allocation of the educational groups was done. Fifty percent of the children were kept in the same school but greater emphasis was placed upon visual methods rather than upon tactual procedures. Some children who had an absolute visual loss could not be changed. Ten percent of the remaining sighted children were placed in sight-saving classes, and about the same number were reconsidered for educational placement after corrective treatment had been done.

It was apparent that insufficient attention had been paid to the partially seeing youngster. Not enough attention had been devoted to each individual child so that he could gain full and complete value from the bit of sight that remained. Too often the youngster was given a routine treatment, was not considered as an individual. No one had attempted to probe the depths of personal differences nor to elicit the heights of personal abilities, which sometimes rose to an undreamed of level.

PSYCHOLOGIC ADJUSTMENT

The last phase of sight restoration is often not classified as such, for there actually is no physical change. There is created no actual physical improvement. It is open to no statistical review. The changes in the person, however, are every bit as valuable and create just as much in the final review as if the person had received more vision. I am referring to the psychologic improvement within the mind of the individual.

Instead of permitting an unseeing child to remain huddled in the corner, our school for the blind has taken him out and put him into direct competition with children possessed of all five senses. For example, one boy, after receiving artificial eyes, could not believe that seeing people on casual inspec-

tion would think that he, too, was like them. He was told time and again that no one knew he had artificial eyes. No. He must have that point proved for himself, by himself.

Wearing both eyes, he went into a men's haberdashery, the best one in that city, and asked for a blue tie. He examined a few ties carefully and then asked for a different darker shade. After looking over the second group of ties, he said that none of them seemed to be the correct shade, that he would search elsewhere for a slightly different color, then left the store.

That experience, a few years ago, was all the boy needed. Now he wears his artificial eyes and is making an excellent social adjustment, just as he is making a satisfactory living by selling books. Almost as much has been accomplished as though more vision had been given.

One girl won her sectional high school oratorical contest—in spite of the fact that she had no eyes. Another boy attends a high school in the same town where the school for the blind is located. He competes with sighted students throughout the day, but his lessons are read to him at night. His grades are entirely acceptable. He goes with the high school athletic teams and attends every game, home or afield. He plays a large horn, marches in all the parades, and is accepted by his fellow students.

This boy has encountered only one minor difficulty—that of marching in parade and drill formation. Even that point was solved by running a fine piano wire from his belt to his adjoining companions. He was forced to that solution one day when his companions turned a corner. He didn't turn, but continued marching straight ahead. Now, when his companions turn a corner, now when the world turns a corner, he turns too, confident of success.

Sight restoration can be of still greater, more widespread benefit than it is today when we realize its full import, its greatest possibilities.

NOTES, CASES, INSTRUMENTS

"TO BALANCE" LENSES

C. Keith Barnes, M.D.
Fort Worth, Texas

The patient was a 14-year-old, auburn-haired, white girl. She gave the history of having pierced the left eyeball with sharp scissors several months previously. The eye was hopelessly damaged and was enucleated elsewhere with the implant of a 16-mm. metal ball into the bulbar fascia. The ball extruded, and was replaced. It extruded again. The original surgeon had suffered a heart attack and was unable to continue with the case, so an interne replaced the ball. In all it extruded five times in less than a year's time.

The socket was markedly shrunken and drained a purulent material constantly. The patient was able to insert only an infant-size prosthesis and, because of the cosmetic disfigurement, preferred to wear a gauze eye-pad. She avoided social activity and felt her disfigurement keenly. She presented herself with the hope that her condition could be corrected.

Eye examination revealed a normal right eye and orbit. A moderately contracted left socket contained a large amount of creamy pus. The skin of the left eyelids, orbital margins, and cheek was badly excoriated. After cleansing the orbit an extensive spider-shaped scar was seen posteriorly in the center of the socket with arms radiating to the cul-de-sac in all directions. The pus oozed from a small ostium in the center of the scar.

Brief exploration at once revealed a small black foreign body which on removal proved to be the end of a 3-cm. fragment of black silk. Saline irrigations of the socket and a bland ointment for the skin were advised. Within a few days the discharge had stopped.

Operation. Since the socket would not accept a satisfactory prosthesis, it was decided to restore it to adequate size with a mucous membrane implant. The girl was nervous and uneasy after her numerous orbital manipulations, but preoperative sedation and local anesthesia were adequate.

The arachnoid scar was dissected out along all of its ramifications, leaving the anterior orbital tissue soft and distensible but lacking much membranous surface. A lateral canthotomy was thought necessary.

The remains of the bulbar fascia were located and the cavity was dilated to adequate size with a large hemostatic forceps. A 16-mm. glass sphere was introduced into the bulbar fascial space and the opening was closed with a 3-0 plain catgut purse-string suture. Bits of surrounding fibrous tissue were imbricated across the purse-string to bury and strengthen the closure.

Hot wet packs were inserted into the socket while the graft was prepared. This was obtained from the lower lip, which throughout was held strongly stretched. An area, 2.5 cm. by 3.5 cm., was outlined and removed in full thickness with a Graefe knife.

The edges of the lip defect were undermined and closed with interrupted black silk sutures; the lip healed rapidly and uneventfully although most of the sutures loosened and were unknowingly swallowed with the food.

The deep face of the graft was carefully denuded of all bits of fat, and the graft was stretched over a prepared and waxed sterile elliptical piece of cardboard cut to size. A small hole had been punched through the center of the cardboard stent to permit possible drainage. The stent was inserted so that the two raw, dry surfaces were apposed. A vaseline gauze pack was snugly forced into the socket. A pressure bandage was applied for 10 days.

At the end of this time the pack was re-

moved, the silk suture clipped, and the stent gently withdrawn. There was considerable foul discharge but, upon cleansing, the graft was seen to be in situ and healthy. The socket was filled with penicillin ointment and the largest possible perforated plastic conformer was inserted. The conformer extruded over night, so it was replaced by a smaller one.

Outcome. The socket healed uneventfully except for one heavy adhesion which had formed under the canthotomy; this adhesion was severed and an effort made to hold the raw surfaces apart with a larger conformer. This failed, so a second graft of mucous membrane was secured from the right cheek, and attached to a stent, and the lateral cul-de-sac was thereby reëstablished.

The resultant socket was healthy and of adequate size but somewhat irregular in shape. Prostheses taken from stock were unsatisfactory, so a special plastic prosthesis was made with an irregular flange trimmed to fit the fornices. After numerous attempts, the prosthesis makers did a beautiful job in matching the opposite eye, and I readily agreed that they had created a masterpiece.

Refraction. The "good" eye was then refracted, with the intention of advising glasses as a protective measure regardless of the optical needs. However, she did need a moderate correction. With the prosthesis, the trial frame, and the right prescription in place I studied her cosmetic effect carefully.

The artificial left eye had a slightly prominent, staring effect, which was found by trial and error to be reduced to normal by a −4D. sph. This, however, made the interpalpebral fissure appear a trifle too short. By trial and error again, it was found that a +2D. cyl. ax. 90° gave the illusion of lengthening the fissure correctly. From the side view her appearance was satisfactory except for a slight retraction of the upper lid.

It was believed that boldness in frame style would draw attention to the frames rather than the eyes, so a gayly decorated frame popular with the teen-age group was selected, a style being found which had a temple to conceal her slight lid retraction.

Result. The result was highly gratifying to all concerned. The young woman has taken a new lease on life, attending parties and public functions with a restored and delightful self assurance. A number of new friends still do not know that she wears an artificial eye, and older friends congratulate her.

DISCUSSION

I have abandoned the custom of prescribing "to balance" lenses before prostheses. I seek instead the prescription which will create the most natural illusion in front of the prosthesis and insist that the opticians grind the lenses as ordered.

Sunken prostheses can be "brought forward" by application of plus spheres. A prominent or staring prosthesis can be minified and recessed by a minus sphere. A palpebral fissure which does not match its fellow can be lengthened, shortened, widened, or narrowed by the use of appropriate cylinders at appropriate axes.

The lateral or profile appearance can be markedly enhanced by a judicious choice of frames and temple positions. The retracted upper lid can be concealed by a high temple. Poor lateral motion of the prosthesis can be minimized by a centrally placed temple. A retraction of the trochlear area can be improved by an oblique cylinder. Prism is justified to elevate a sagging prosthesis.

As a general rule, plastic frames do more to create a cosmetic illusion, particularly if they are fairly massive and have strong color or accents. The frame width should usually be kept more narrow than one would customarily use, since the concealment effect is better.

Probably many hundreds of cases would lend themselves yearly to this cosmetic consideration. One patient with von Recklinghausen's disease and profound distortion of the left orbital area was similarly pleased by a careful choice of glasses. He needed a

minor correction for the right eye, so a pair of very massive frames carrying moderately tinted lenses was chosen. A special left temple was decided upon because of his deformity, and he was given both psychologic and cosmetic benefit. Since the left eye was useless, bulging tissues were minified by a minus sphere.

Blind, staphylomatous eyes can be made less obvious by minus spheres. Blind shrunken eyes can be tried with plus spheres. Tinted lenses can be used where needed without detracting from the effect. It is possible to put a light shade over the "good" eye and a somewhat darker shade over the other with hardly noticeable effect.

I claim no originality for these thoughts; they have all been suggested and tried by others. However, investigation has shown that many ophthalmologists have never considered nor even heard of these simple cosmetic aids. I feel that results can be so gratifying that this small detail deserves studied consideration in every suitable case. Let us abandon the "to balance" prescription!

A MODIFIED TECHNIQUE OF TARSORRHAPHY*

M. SARWAR, M.B.B.S.
Oxford, England

The value of tarsorrhaphy in indolent corneal conditions, in muroparalytic keratitis, and in plastic surgery needs no mention. The standard technique of tarsorrhaphy both as described in textbooks and practiced involves a loss of tissue (freshening of the lid margins—Wheeler; cutting out planned areas of tarsal plate—Elschnig) and, unless this removal of tissue is carried out fully, the tarsorrhaphy fails. This loss of lid tissue in temporary tarsorrhaphies is a great disadvantage because of the lid deformities that are sometimes caused.

TECHNIQUE

I have been able to modify the technique slightly, so that there is no taking away of tissues and no chance of failure. I have been practicing this technique with success for over three years. I hope it will appeal to other colleagues and will be given a fair trial.

The instruments required are: (1) 2-cc. hypodermic syringe and needles for infiltration; (2) lid clamps; (3) Beer's knife; (4) black silk (4-0) on No.-3 needles; (5) short length of 1-mm. rubber tubing; (6) needle holder and forceps.

Preparation. The skin of the lids is prepared in the usual way. The lashes may or may not be cut; it is an advantage not to cut them.

Anesthesia. Local anesthesia of conjunctiva is obtained by 4-percent cocaine or any other substitute (anethaine, and so forth). Both the lids are then infiltrated with a suitable infiltration anesthetic. I usually use Novatox. For median tarsorrhaphy and complete tarsorrhaphy, a few drops should also be injected along the medial wall of the orbit.

Operation. With the usual aseptic precautions, one of the lids is held in the clamp firmly. I usually start with the lower lid first. The gray line is then defined, and an incision made along it, separating the tarsal plate from the skin and orbicularis. The length and site of this incision will depend on the length and site of the lid occlusion required. The separation of the tarsus is carried out to about one third of its width; that is to about 3 mm. from the margin (fig. 1). The clamp is now applied to the other lid, and a similar splitting of the lid is done.

A continuous mattress suture is now inserted, biting the pretarsal tissues (fig. 2). The suture is drawn tight, but the ends are left free. This brings the two tarsal plates together at their edges and covers the eye.

The free, lash-bearing edges of the lids are now sutured together with interrupted mattress silk sutures (fig. 3). These sutures

are drawn through 3-mm. lengths of the rubber tubing and tied tight (fig. 4).

The lids are now cleaned and dressed with penicillin Tulle Gras. The dressing is
Fig. 1 (Sarwar). Holding the lid firmly in the clamp, an incision is made and the separation of the tarsus is carried out to about one third of its width.
Fig. 2 (Sarwar). A continuous mattress suture is inserted, biting the pretarsal tissues.

changed in 48 hours, when the continuous pretarsal suture is pulled out. The new dressing is left on for 6 days, and the skin stitches are removed at the end of that period.

Postoperation anatomy. The lash-bearing margins of the two lids are directed anteriorly. The orbicularis fibers of the two lids are united together by fibrous tissue; the union is about 2-mm. wide and is along the whole length of the operated area.

DISCUSSION

The operation is very simple to do and requires very few instruments. The lid clamps can be dispensed with if not readily available.

It does not involve removal of any tissues —a point of considerable importance in temporary tarsorrhaphy.

It does not interfere with the anatomy of the tarsus—another important point in temporary procedures. When a temporary tarsorrhaphy is undone, the skin and tarsus
Fig. 3 (Sarwar). The free, lash-bearing edges of the lids are sutured together with interrupted mattress silk sutures.

Fig. 4 (Sarwar). The sutures are drawn through 3-mm. lengths of rubber tubing and tied.

unite together again in their natural state, with no residual deformity of lid margin.

The union of the two lids is by connective tissue and about $\frac{1}{2}$ to 1 mm. behind the lash-bearing area, the two rows of lashes diverging from the line of union, and curving up and down respectively. The cosmetic effect

in a total tarsorrhaphy, although strange, is not unpleasant as with the more usual procedures. For the same reason the cosmetic effect is definitely superior in partial tarsorrhaphies, the eye acquiring a "dreamy" look, rather than the "tampered with" appearance of the usual procedures. The presence of the lashes hides the scar of union, too.

The greatest advantage, however, is the permanence of the procedure. It is, permanent because the union is a fibrous one between the orbicularis muscle fibers, and there is no tension on the skin.

In cases of muroparalytic keratitis, the lid sutures should not be tied too tightly, or else the already atrophic skin might die and slough away, causing a scar.

USE OF PRIVINE-ANTISTINE DROPS IN OPHTHALMOLOGY*

RAY K. DAILY, M.D.,

AND

LOUIS DAILY, JR., M.D.

Houston, Texas

This is a combination of two drugs,[†] Privine and Antistine.

Privine is chemically a naphthyl-methyl-imidazoline hydrochloride. It is a crystalline colorless substance soluble in water and in saline solution. The solution is stable and is not decomposed by exposure to light or air. Its pharmacologic properties were described in 1941 by Meier and Müller.

Instilled into the conjunctival sac it produces a vasoconstriction similar to that of adrenalin; it lasts longer and there is no secondary vasodilatation. The blanching of the conjunctiva sets in rapidly, lasts about 2 to 3 hours, and then slowly recedes; it acts

principally on the small conjunctival vessels. The effect on the larger vessels and on the ciliary and episcleral vessels is less pronounced.

It is a sympathetic stimulant and produces a slight widening of the palpebral fissures through contraction of the musculus tarsalis superior. It also produces a perceptible pupillary dilatation by its effect on the dilator pupillae. The mydriasis is noticeable only in dim light and in eyes with blue irises. In daylight and in brown eyes the mydriasis is uncertain. It disappears in several hours and does not cause dazzling. The pupillary reactions, accommodation, and corneal sensitivity remain normal.

The effect on the intraocular pressure is insignificant. Bürki[2] in the report of his clinical investigations states that he did not see a single case of a rise in intraocular pressure. Fanta[3] of the Lindner Clinic found a few cases in which the instillation was followed by a brief and insignificant increase in tension.

Antistine, a synthetic antihistaminic drug, is a crystalline, white odorless powder, the chemical formula of which is phenyl-benzyl-aminomethylimidazoline. Its sulphate, used for the ophthalmic solution has a pH of 6.9. It is prepared in an isotonic buffered solution with the following formula—antistine sulphate, 18.75 gm.; sodium carbonate anhydrous, 2.66 gm.; potassium chloride, 27.75 gm.; boric acid, 46.50 gm.; distilled water, 3,750 cc.

Bourquin[1] reported on the use of this solution in 37 cases of various types of conjunctivitis and scleritis. He found that its instillation relieved photophobia, itching, and lacrimation, and was of value in giving symptomatic relief, although it had no permanent effect on allergic conditions.

A combination* of 0.5-percent Antistine with 0.025-percent Privine has been used by us in about 100 cases of various types of conjunctivitis.

Its vasoconstricting effect and its calming action on blepharospasm make it useful in a number of conjunctival and corneal diseases. The effect varies in different patients, both as to intensity and duration. Its instillation produces a short transitory smarting sensation. One patient with keratoconjunctivitis sicca, on whom it was tried, complained that after the instillation of the solution the eyes burned for a considerable period of time, but that the eyes were very comfortable for some time afterward.

The solution is particularly suitable for cases characterized by conjunctival congestion. It is used gratefully by patients who complain of burning, itching, photophobia, lacrimation, or dryness, a sensation of sand in the eyes, fatigue and blurring of vision, particularly in the evening.

In most of these patients the objective data are not commensurate with their subjective symptoms. In many cases there is no objective pathologic condition; the conjunctival scrapings are negative for microörganisms; the lacrimal passages are normal; the refractive error is corrected.

In some cases there is a mild subacute or chronic conjunctivitis with moderate redness and swelling of the palpebral and fornix conjunctiva. Occasionally, there is more pronounced conjunctival hyperemia and infiltration with a few follicles. In such cases instillation of Antistine-Privine drops every four hours brings prompt subjective amelioration. The alleviation of subjective complaints is superior to that obtained from the instillation of weak zinc sulphate, resorcin, or mercury oxycyanide, the medicaments which usually give transitory relief to such patients.

Since Antistine-Privine solution may be used indefinitely, it is a useful addition to our list of medicaments for chronic conjunctivitis. It is appreciated by patients with allergic conjunctivitis, who complain of photophobia and lacrimation. In eczematous keratitis, it is said to reduce the inflammatory symptoms by decongestion of the conjunctiva, and to diminish the corneal vascularization with a salutory effect on the visual outcome.

The solution may be combined with astringents in chronic conjunctivitis, or with silver preparations in acute conjunctivitis. In scleritis and episcleritis the bulbar congestion is reduced, and the patient gets a sense of subjective improvement, but the effect is not as pronounced as it is in conjunctivitis. It is also useful for the relief of postoperative discomfort due to persistent conjunctival hyperemia.

In persistent conjunctival irritation following trauma, burns, and chemical injuries, the instillation of the drops causes a blanching of the conjunctiva, and gives the patient a sensation of relief. In combination with local anesthetics, such as pontocaine or holocaine, it reduces the conjunctival irritation frequently produced by these anesthetics. This is an advantage when repeated applications are necessary, as in taking tension curves. It can also be used in place of adrenalin instillations in surgical procedures.

SUMMARY

The combination of Antistine-Privine drops is a valuable addition to our therapeutic armamentarium. Instilled into the conjunctival sac it produces a rapid decongestion of the conjunctiva, which is agreeable in a number of conjunctival conditions.

ACCIDENTAL CYCLOPLEGIA BY JIMSON WEED

LUCIAN BAUMAN,* M.D.

Washington, D.C.

The solanaceous plant, Datura stramonium, also known as Jimson weed, stink weed, Jamestown weed, is widely distributed in the United States and in many parts of the world. Containing mainly hyoscine, it has been used since the earliest times for its systemic effects. Tradition has it that this was the drug given to the person delivering the oracle in the Temple at Delphi.[1]

During the summer and fall small children playing in the gardens and woods are attracted by this large weed and its fruit, and, mistaking it for some edible fruit, eat it in relatively large amounts. Although there are many reported cases of either accidental or criminal poisoning by ingestion of stramonium every year, there are only seven reported cases of accidental cycloplegia in the world literature during the past 50 years; 3 in the United States,[2,3] 1 in Cuba,[4] 1 in France,[5] and 2 in French Morocco.[6] All occurred in adults.

It is my suspicion that there are many more cases of sudden unexplained cycloplegia (and mydriasis) that are caused by parts of the leaves and seeds of the Jimson weed getting into eyes.

CASE REPORTS

The following cases occurred in children.

* Of the resident staff, Department of Ophthalmology, Gallinger Municipal Hospital.

Case 1.† A very intelligent, 11-year-old girl was recently brought into the eye clinic of Gallinger Municipal Hospital because of sudden loss of vision in the right eye. The girl stated that while playing in the nearby woods the previous afternoon she had kicked at some tall weeds and that the large pods on the plant had burst showering her head with seeds. In shaking them off something had gotten into her right eye. That evening she complained to her grandmother who thereupon found and removed a small black seed from the eye.

The next morning the patient noticed the blurred vision in the right eye and her grandparents noted the dilated pupil. She was brought to the clinic that afternoon. The child brought a segment of the weed complete with pods and the grandfather volunteered the information that the plant was very common in the vicinity and was known as the Jimson weed.

Ocular examination revealed mydriasis and cycloplegia of the right eye. Within 48 hours the pupil and accommodation had returned to normal.

Case 2. Three weeks previously, a 12-year-old boy had been examined. The same type of condition was presented, and it followed the same course. Here, no explanation could be obtained of the phenomenon, the parents stoutly maintaining that no eye drops were ever in the house. The strongest suspicion now points to the Jimson weed as being the offender.

2601 16th Street, N.W. (9).

SOCIETY PROCEEDINGS

Edited by Donald J. Lyle, M.D.

INDICATIONS AND RESULTS IN KERATOPLASTY

Dr. Harold G. Scheie reported the results obtained from 22 corneal transplant operations performed at the Hospital of the University of Pennsylvania. Nineteen of the eyes were followed through convalescence and the statistics presented were obtained from these, although it was realized that the number was too small to be of statistical significance. The cases were classified according to Castroviejo's prognostic grouping from Group I, the most favorable, to Group IV, the least favorable.

Three criteria were used to judge the success or failure of the operation: (1) clarity of the graft, (2) improvement in visual acuity, and (3) benefit to the patient.

Six eyes operated were of Group I, including those having a central corneal scar from old keratitis, keratoconus, and one having central scars from interstitial keratitis. All of the patients in Group I obtained clear grafts and improved visual acuity which was very striking in three. When improvements did not result, amblyopia ex anopsia or central scotomas offered the explanation.

The criterion of actual benefit derived from the operation by the patient offers an even more critical and possibly more practical way of evaluating corneal transplantation. In spite of clear grafts and visual improvement in all, only 4 of the 6 patients used the operated eye, thus deriving benefit from the procedure. The astigmatic error varied from 2 to 5 diopters.

Only 3 of the 4 patients in Group II have completed their convalescence. Two of these 3 have clear grafts. All have rather remarkably improved vision, but only 2 of the 3 obtained real benefit from the operation, the third not using his operated eye.

There were only 2 patients in Group III. The first patient had been suffering from recurrent corneal ulceration with severe discomfort for three years. He had reached the point where he preferred enucleation of the eye rather than further discomfort.

The involved area of the cornea was central. A corneal graft was done which remained clear and has made him more comfortable. There was no visual improvement, however, because of a complicated cataract which had been present before operation. He should have a good eye following the extraction.

The other patient had central scarring from an old keratitis, but the lens had been subluxated by a former injury, and was cataractous. A transplantation was done in the hope of giving him a clear cornea before cataract extraction, but the graft became opaque, and he has definitely been made worse by the operation.

Group IV included 8 patients with severe corneal conditions such as epithelial dystrophy, severe corneal degeneration as a result of interstitial keratitis, extensive mustard burns of the cornea, and one recurrent ulcerative keratitis with calcareous degeneration.

Only 1 of these has a clear transplant, and 3 obtain significantly improved vision. However, from the standpoint of benefit to the patient, 4 of the 8 have been dramatically improved either visually or through alleviation of symptoms. The most dramatic was that of a soldier with bilateral severe mustard burns of the cornea. Only 1 patient, who developed an iris prolapse with eventual loss of his eye, was made worse by the procedure.

Taken as a whole, visual improvement

444

was obtained in 65 percent of patients. Fifty percent of the grafts remained clear. From the standpoint of benefit to paients, 56 percent of the patients were benefited by the operation. Thirty-one percent were unimproved and 10 percent were made worse, although this is difficult to say since their vision had been hand-movements and light perception respectively before operation. Since 8 of the patients operated were in Group IV, the overall figures are not displeasing.

The indications followed for corneal transplant were:

1. Favorable conditions of Group I and Group II are preferred, but whenever a patient has a chance of some visual or symptomatic gain and nothing to lose, corneal transplantation can justifiably be done.

2. Vision should be less than 6/60.

3. Hesitation is advised in unilateral involvement.

4. A one-eyed patient should be operated only if his eyesight is of no practical value to him.

Discussion. Dr. James S. Shipman: I would like to congratulate Dr. Scheie on this excellent and very honest presentation of a most interesting subject. Indeed the picture of keratoplasty, as given here tonight, is very different from that we see given to the public too often in the newspapers. I think it is too bad that the subject cannot be presented to the public, through the newspapers, in its true light.

The actual cases as presented here tonight are evidence of the excellent technique followed by Dr. Scheie. Indeed they are very convincing for the circular type of transplant.

One of the cases presented here tonight happens to be that of a patient on whom I did a corneal transplant about six years ago. At that time we used the double-bladed knife of Castroviejo and obtained a square graft. In this case everything went well until about a week after operation, when the patient developed a secondary glaucoma. This

was eventually controlled with miotics. I notice that Dr. Scheie encountered this complication only once in his series of 20 cases.

The patient of whom I speak had presented a most severe case of interstitial keratitis. A short while after operation he developed a marked increase, and overfilling, of old corneal vessels. As a result of this, the corneal graft went on to complete opacification. We had given this patient numerous X-ray treatments recently with the hope of blocking off the corneal vessels, and had planned to try a second transplant. I am very happy to see that Dr. Scheie has done this, and I hope that his results are satisfactory. I also hope that he will do a similar operation on the other eye which is less scarred and vascular and offers a better prognosis.

Indeed after seeing the cases presented here to night I feel that Dr. Scheie is to be complimented on his beautiful technical results, and I am sure that, with more favorable cases, the visual results will be better.

Again I wish to say that this paper has been most instructive and enjoyable.

Dr. W. E. Fry: There are a number of interstitial keratitis cases at the Overbrook School and, in breaking down some of the statistics in regard to them several years ago, the general outlook was poor in regard to corneal surgery. Many of the patients showed evidence of severe anterior uveitis and, when the fundus was visible, showed optic atrophy.

There is one point that I think might be added to the discussion, and that is we probably do not know the full story in regard to how the transplant acts as a foreign body in the cornea. The reason why I make the statement is this—one youngster with an interstitial keratitis on whom I did a transplant on both eyes had a 6/9 vision in one eye following surgery, and has maintained this vision for over one year. Six months later I did the second eye with exactly the same technique with no complications whatsoever. The result was a partially opaque cornea

and 6/60 vision. I cannot explain the difference. I wish Dr. Scheie would explain it to me. I think there is something we do not know in regard to the way in which we select our donor material.

Dr. Hunt: It has been my privilege to look at all of these cases that Dr. Scheie has done, I believe, and follow them through, and while the procedure is not technically too difficult, anyone who is not prepared to do very thorough and meticulous after care should not attempt the operation.

I believe Dr. Scheie mentioned there were some 60 complications in this series. From his discussion, I think we can evaluate this as being a practical, useful procedure that should be tried in favorable cases.

Dr. Louis Lehrfeld: The oldest case of corneal transplant that I have on record is one dating back to the year 1940. This case was one of keratoconus in which the transplant was regarded as quite successful. The patient's vision was partially restored by the transplant. The patient, who was seen by me and my associate only a few weeks ago in the clinic, now has keratoconus recurring in the transplant itself. I mention it, because I think that those who are now doing the transplants should keep in mind the fact that mere transplantation of a good cornea to take the place of an old one does not necessarily change the fundamental pathology underlying keratoconus. That does not mean necessarily that one should be discouraged in doing this type of operation for keratoconus or for any other cause.

The essayist has suggested to you various types of corneal lesions for which he would propose to do a corneal transplant. Of course, it has been said facetiously and I have heard the remark passed many times at conventions, that when you get good transplant results it might have been possible to get similar results by doing something else instead of the transplant. I would like to encourage further experimental work in transplants because the future holds much for it. Despite the fact that there are many dis-

appointments and many unusual cases of improvement, I feel that in the future many more cases, even in Groups III and IV, will be successful.

Dr. Harold G. Scheie (closing): I wish to thank all of the discussors. Vascularization of the transplanted cornea is the biggest problem with which we have to deal. The explanation for this vascularization has always been obscure, but might be derived from the experience of the general plastic surgeon who finds that skin transplanted from one individual to another apparently takes well for approximately three weeks. After this time it exfoliates and is lost, not being tolerated by the recipient's tissues.

It is at about this same time interval that eyes on which corneal transplantation has been done become red; the graft tends to become cloudy, and blood vessels invade the cornea. This reaction and vascularization is less severe in corneas where vessels have been minimal preoperatively.

On the other hand, if the cornea was heavily vascularized beforehand, the eye seems to do well for about 2 to 3 weeks, then becomes inflamed and the graft rather rapidly vascularizes. The transplants, as a result, become opaque in a rather large number of cases. The reaction of the recipient to tissues from another of the same species might well correlate with the number of preexisting vessels into the recipient bed, the tissue responses being greater where vascularity is excessive.

SOME OBSERVATIONS ON MIOTICS

DR. EDWIN B. DUNPHY of Boston (guest speaker).

This paper appears in full on page 399 of this issue of the JOURNAL.

Discussion. Dr. Francis Heed Adler: I think we are all very appreciative of the able way in which Dr. Dunphy has covered this entire field in both the theory and practical use of miotics. The point he brought out about mecholyl is evidence that the increased pressure in glaucoma damages the post-

ganglionic fibers so that the myoneural junction becomes sensitive to cholines.

Dr. Scheie has previously reported the experimental production of sensitivity to mecholyl in cats by artificially raising the intraocular pressure for short periods of time. It is generally supposed that such sensitization does not occur until nerve fibers have degenerated and, if this is so, one would hardly expect mecholyl to be of use in an acute glaucoma when the attack has lasted only an hour or so. Actually, it seems to be effective in this condition, and this, combined with Dr. Scheie's experiments, suggests that it is not necessary for nerve degeneration to take place in order to produce sensitivity.

Dr. Irving H. Leopold: This paper represents one of the best summaries of miotic therapy in glaucoma and of pharmacologic data on miotics.

I was very interested in Dr. Dunphy's discussion about T.E.P. triethyl-pyro-phosphate. In 1934 there was an epidemic of diarrhea and peripheral palsies in the inhabitants of one of the islands of the West Indies, and for a long time they were perplexed as to the etiology. It was then found that these individuals were eating or working with Jamaica ginger, and I believe one of the compounds which was extracted from the ginger was tri-ortho-cresyl phosphate. This was found to have marked anticholinesterase activity by some Swedish workers just a few years ago. It may be that this drug or one of its derivatives also might merit evaluation in ophthalmology.

Dr. Dunphy considered the question of synergism of cholinergic and anticholinesterase drugs. It is interesting to consider the effect of combining two anticholinesterase drugs such as eserine and D.F.P. It can be shown that eserine blocks the action of D.F.P.

A series of animals were injected with D.F.P., and the minimal lethal dose of D.F.P. that will kill about 50 of every 100 animals was determined. If another series

of the same animal were given a sublethal injection of eserine, it was found that the previously used dose of D.F.P. no longer killed those animals. In other words, eserine had protected the animals from the lethal action of D.F.P.

The same phenomena can be demonstrated in the eye by instilling a drop of eserine in one eye of an individual, wait until the maximal miotic effect has occurred, which usually takes about 15 minutes, and then instill a drop of D.F.P. in each eye. The eye which has received eserine comes back to preinstillation size in about 2 to 3 days. The eye which has received D.F.P. alone remains miotic a week or two, the usual length of time for the D.F.P. miotic effect.

Now what about the reverse effect, that is if D.F.P. is used before eserine? The sublethal dose of eserine is determined. That is the intramuscular dose that just fails to kill. Animals are given an injection of D.F.P. in a similar sublethal dose. Following this the previously determined sublethal dose of eserine is injected. The eserine injection now results in the death of most of the animals.

In other words, D.F.P. does not prevent the action of eserine. Actually, when eserine is given after D.F.P. there is a combined effect.

One of the experiments that interested me was the one that employed the ingenious method of instilling eyedrops in the dark. The observation that D.F.P. did constrict the pupil of the dark-adapted eye does not mean that D.F.P. has a direct effect on iris musculature, but simply that even the dark-adapted eye produces acetylcholine that can be preserved when D.F.P. ties up the cholinesterase.

This was certainly a very enjoyable paper.

Dr. I. S. Tassman: I would like to make one or two remarks in connection with Dr. Dunphy's observation, particularly regarding the increase in intraocular pressure following the instillation of these miotics, and also regarding the effect on the vessels. I have under observation at the present time at

Wills Hospital one case in which we noted an increase in the intraocular pressure following the instillation of mecholyl and neostigmine and, in addition, the lens in the affected eye was pushed so far forward that the anterior chamber was almost entirely obliterated.

I also recall another case in which we observed an increase in the intraocular pressure following the use of D.F.P.

It is interesting to speculate as to the mechanism by which the intraocular pressure is lowered by these drugs. As was pointed out, I think also that there are certain differences in the action of these various drugs when they are employed in certain combinations. This is probably true of those in the adrenergic group, as well as those belonging to the cholinergic group. Some time ago, I think Dr. Cogan published an article in the *Archives of Ophthalmology* which had something to do with the dual intervention of the ciliary body. In that paper I believe Dr. Cogan referred to the use of these miotics. In another article, I believe it was by Myerson and Thau, speculation was made as to the possibility of an overaccumulation of the esterases with oncoming age to explain the occurrence at that age of presbyopia.

A fair amount of progress has been made since the work of Loewi and Englehart, Cogan and others, but the mechanism is still quite complex, as Dr. Dunphy pointed out, and as yet not fully understood. I think that Dr. Dunphy should be congratulated for this very comprehensive, interesting, and practical paper. It has been a great pleasure to hear it.

Dr. Edwin B. Dunphy (closing): I was very much interested in what Dr. Leopold said about the eserine and D.F.P. combination.

There is very little for me to say, Mr. Chairman, except to thank you again for your invitation.

M. Luther Kauffman,
Clerk.

NEW YORK SOCIETY FOR CLINICAL OPHTHALMOLOGY

March 1, 1948

Dr. Daniel Kravitz, *president*

VISUAL FIELD STUDIES IN NEURO-OPHTHALMOLOGY

Dr. Max Chamlin discussed this subject during the instruction period.

PUPILLARY ABNORMALITIES ASSOCIATED WITH INTRACRANIAL LESIONS

Dr. Abraham Rabiner said that a neurologic examination is never complete without careful study of the pupils. A dilated pupil may be the only clue as to the hemisphere affected by subdural hematoma or other type of expanding intracranial lesions. That abnormal pupillary responses to light may be the only objective evidence of central nervous disease syphilis has long been known. The Horner syndrome often localizes the pathologic process at the cervical cord level. This occurs also in lesions of the medulla and of the lung apex.

The wide-open, staring eyes and dilated pupils of the panicky individual may be compared to the exophthalmos in the goiter patient. The mechanism controlling pupillary innervation is highly labile. The autonomic nervous system may be regarded as the neural apparatus determining the instinctive somatic reactions to each bit of life experience. All stimuli producing emotional reactions travel through the sensorium up the spinal cord or through the other perceptive pathways to the brain stem, the basal ganglion structures, and the cerebral cortex and also travel with the vascular tree.

It seems obvious, therefore, that it is not justifiable to speak only of centers where lesions produce a Horner syndrome. It is, more accurate to think of pathways conducting stimuli that are either interrupted or stimulated. Such stimuli may be of a structural organic nature but often are psycho-

genic. Life itself and its kaleidoscopic events frequently affect the nervous system and amongst other symptoms produces alterations in the appearance and reactions of the pupil.

ALTERATIONS IN EXTRAOCULAR MOVEMENTS RESULTING FROM INTRACRANIAL LESIONS

DR. E. JEFFERSON BROWDER said that the aneurysms arising from the intracranial portion of the internal carotid artery, those budding from the arteries comprising the circle of Willis, and those of the basilar artery and some of its branches, often impinge upon and produce dysfunctions of the third, fourth, and sixth cranial nerves. Other aneurysms not adjacent to those nerves may produce extraocular palsies secondary to rupture into the cerebral subarachnoid space or into the cerebral substance, with massive clot formation.

Dr. Browder said that an analysis of the symptomatology and abnormal physical signs with particular reference to extraocular palsies indicates that six different syndromes may be recognized:

1. The syndrome of rupture of the aneurysms of the internal carotid artery as it traverses the cavernous sinus or the carotid-cavernous fistula.

2. The syndrome of the aneurysms of the second part of the sigmoid of the internal carotid. The intracranial epidural fusiform aneurysms.

3. The syndrome of the aneurysms of the subdural portion of the internal carotid artery.

4. The syndrome of the aneurysms at the bifurcation of the internal carotid artery and those of the posterior communicating artery.

5. The syndrome of intrancranial hypertension resulting from aneurysmal rupture (spontaneous subarachnoid hemorrhage and/or intracerebral hematomas).

6. The syndrome of fusiform aneurysms of the basilar artery.

While it is recognized that all abnormal features must be given consideration in any

example of intracranial aneurysm, a correct interpretation of the disturbance in the ocular mechanism plays an important role in the localization of such a lesion.

MONOCULAR AND BINOCULAR PALSY OF GAZE

DR. ALFRED KESTENBAUM said that horizontal palsy of gaze or palsy of lateral parallel eye movements is characterized by impairment of the lateral gaze movement while the convergence movement of the eyes is preserved. The types of lateral gaze movement are:

1. Command movement, movement on a command, such as: "Look to the right!" This is also known as schematic movement.

2. Optically elicited movement; that is, movement toward a seen object. This is also known as follow movement.

3. Compensatory eye movement on head rotation due to a labyrinth reaction. This is also known as vestibular movement.

Horizontal gaze palsy may involve the lateral rectus of one eye and the medial rectus of the other eye to the same degree. This is known as the congruous form of gaze palsy. The incongruous form of gaze palsy may affect one of the two muscles to a different degree or the medial rectus alone.

Dr. Kestenbaum then cited a series of his own cases and cases taken from the literature which illustrated the following types of congruous gaze palsy.

1. General palsy of lateral gaze in which all main types of movement are abolished.

2. Bielschowsky type of gaze palsy in which labyrinthine countermovement is preserved, while the other types of movement are abolished.

3. Oppenheim's type of gaze palsy in which vestibular movement and follow movement are preserved and schematic movement is abolished.

4. Isolated lesion of schematic movement in which vestibular movement and follow movement are preserved, only schematic movement being abolished.

In these types of congruous gaze palsy,

the medial rectus of the one eye and the lateral rectus of the other eye are involved to the same degree, and the convergence movement is normal.

Incongruous gaze palsy was observed in the following forms:

1. Foville's syndrome. The right eye cannot be adducted in lateral gaze but it can be adducted on a convergence impulse; the left eye cannot be abducted and shows paralytic squint. This proves that in addition to the lesion of the posterior longitudinal bundle, along which run the lateral gaze impulses, the abducens nucleus or abducens nerve is involved.

2. Intranuclear gaze palsy. Adduction of the right eye is more disturbed than abduction of the left eye; convergence is normal. The lesion is usually considered to be in the left posterior longitudinal bundle between the level of the sixth-nerve nucleus and that of the third-nerve nucleus, but close to the former one.

3. Supranuclear medialis paralysis or superior intranuclear gaze palsy. Adduction of the right eye in attempted lateral gaze is abolished. But in attempted convergence, normal abduction of the left eye is normal. This lesion is also localized in the left posterior longitudinal bundle, but higher up than in the previous form.

In a case of supranuclear medialis palsy, a paradoxical phenomenon was seen. In binocular vision, the left eye could not look at any object on the right side, but when the right eye was closed, the left eye could turn toward the object. This movement was achieved by a convergence impulse, because the covered right eye was found to stand in adduction and the pupils were narrowed. Hence there was a substitution of a convergence movement for a lateral movement. Of course, this could be shown only when the right eye was covered so that no diplopia occurred.

4. Bilateral intranuclear gaze palsy. In this case both medial recti do not work in lateral gaze but do in convergence. This syndrome is significant for a median lesion involving both posterior longitudinal bundles between the third-nerve nucleus and the sixth-nerve nucleus.

Dr. Kestenbaum summed up by saying that all these forms of incongruous gaze palsy involve all the main forms of gaze movements to the same degree.

Bernard Kronenberg,
Recording Secretary.

OPHTHALMOLOGICAL SOCIETY OF MADRID

March 12, 1948

HYSTERICAL BLINDNESS

DR. MARIN AMAT AND DR. MARIN ENCISO discussed a recent case which showed the importance of careful and conservative diagnosis and treatment in this condition. A young woman, aged 23 years, suffered complete loss of vision in both eyes after a quarrel with her fiancé. The eyes and adnexa appeared to be completely normal.

As her vision began to return, it was possible to map the very reduced central visual field, the inversion of the red and blue fields, the classical field curves of Foerster, fatigue curves of Vilbrand, and so forth.

Psychiatric treatment together with vitamin therapy restored her vision and general equilibrium.

Discussion. Dr. D. Sinforiano Garcia Mansilla said that the case was interesting since it began as an amaurosis and then developed into amblyopia, permitting visual field tests for white and colors.

Many years ago he had published a case of hysterical blindness in a man who presented the following history. He was a student of timid nature who, in the evening before taking a final examination at the academy, suddenly became completely blind.

Eye examination, in which three colleagues assisted, established the presence of complete blindness, the absence of any lesion, and the retention of pupillary motility. These three symptoms pointed to hysterical blindness.

Previous nervous manifestations of the patient were that during the previous year, while explaining an equation on the blackboard at an examination, his vision suddenly became bad, the blackboard appearing red and the chalk green, and he had had to ask the proctor to permit him to rest. After a little rest, he recovered, saw the blackboard and chalk in their natural colors, and proceeded with the examination.

This history made the diagnosis plain. The patient was given a placebo and suggestive treatment. One week later, after a quiet sleep, his sight returned completely.

This is a typical case of hysterical amaurosis with the classical triad of symptoms: sudden blindness, normal fundus, and persistence of pupillary reaction. To these three may be added a fourth symptom—sudden and total recovery.

Dr. Munoz Pato: Given the psychic disturbances that characterize hysteria, one should be prudent both in diagnosis and treatment. Although mild cases can be quickly cured in one session (by instillation of drops, utilization of some complicated instruments, and so forth), other cases are more complex and serious. In these, simple methods will fail and the longer procedure of Dr. Marin Amat and Dr. Marin Enciso must be resorted to.

Dr. Marin Amat said that he does not use the word "hysteria" with either men or women but prefers the term proposed by Babinski, "pithiatism," which implies that the condition is curable by persuasion.

To be sure, the triad of symptoms, sudden blindness, normal fundus, and retention of pupillary reflexes, indicate hysterical amaurosis. There are some conditions, however, that exhibit these symptoms and are not of hysterical nature. Such a one, for example, is uremic amaurosis from lead poisoning. In this instance, the changes are in the visual cortex. The optic fibers that pass to the anterior colliculus and from there to the nucleus of the third nerve and that subserve the pupillary reflexes are not affected. According to Charcot, we find in hysteria a narrowing of the field of consciousness, a narrowing of the field of vision, and an unfolding of the personality.

Dr. Martin Amat agreed with Dr. Munoz Pato that there are always certain phases of a neurosis in hysterical amaurosis. Application of psychiatry should, however, be reserved for special cases. In the ordinary cases, the ophthalmologist should have enough general and psychiatric knowledge to treat the condition.

ERB-GOLDFLAM DISEASE

DR. BARTOLOZZI presented two patients, a mother and daughter, with the typical picture of pseudoparalytic myasthenia or Erb-Goldflam disease. The girl showed marked bilateral ptosis and almost total paralysis of the extrinsic musculature of both eyes, with perfect preservation of the power of the intrinsic eye muscles.

The mother showed pseudoparalysis of the muscles of the lips, tongue, and larynx. Electrical exploration disclosed the nuclear origin of both processes. The myasthenic reaction was negative, but the clinical picture, the improvement of the condition by rest, its aggravation during the day, as well as the amount of creatine in the urine, all testified that it was a case of myasthenia, although different clinical pictures were present in mother and daughter.

NEVUS PIGMENTOSUS IN A PYTERYGIUM

DR. MARIN AMAT AND DR. MARIN ENCISO demonstrated the case of a 48-year-old peasant who for 30 years had had a little black spot on the conjunctiva of the left eye near the sclerocorneal margin at about the 9:30-o'clock position.

This spot did not give him any trouble but when he developed a pterygium in this eye several years ago, the spot seemed to increase in size. The pigment spot was removed during the operation on the pterygium. The laboratory diagnosed it as nevus pigmentosus.

INTERNATIONAL CONGRESSES

For the physician tourist an international congress combines the stimulation and recreational delights of travel with the deepened sense of fellowship between professional colleagues. There are the teachers and thinkers whom we have perhaps known only through the printed page or by the medium of casual correspondence. Sometimes, it is true, these may disappoint us and take on less significant stature, physically or intellectually, than they had carried in our imaginations before the personal encounter. On the other hand we now and then enjoy the pleasurable stimulus of becoming acquainted with brilliant personalities never revealed to us through medical journals; for there are many such among our great profession in general and our specialty in particular. It is unfortunate that some of the friendships thus created suffer too easily the attrition due to time and space.

The First International Congress of Ophthalmology, held in Brussels in 1857, must have displayed the wonderful freshness of knowledge, discovery, and enthusiasm associated with a decade of study in the revelations of ophthalmoscopy. At that time

this technique of examination was still sufficiently youthful to have acknowledged a period during which the master Graefe had regarded glaucomatous excavation as a protrusion of the optic disc (an impression which he soon revised). There followed the Paris Congress of 1862, the first Amsterdam Congress of 1867, London in 1872, New York in 1876 (Herman Knapp as a shining light), Milan in 1880, Heidelberg in 1888, Edinburgh 1894, then Utrecht (Holland) 1899, Lucerne 1904, Naples 1909.

War of course interfered with the regular succession and sometimes with place of meeting. There had been the Franco-Prussian conflict. World War I clashed with the arrangements for the twelfth Congress, planned for St. Petersburg (now Leningrad) in 1914. The very successful second Amsterdam Congress fell about midway between World Wars I and II, in 1929. The fourteenth Congress, in Madrid, 1933, was a few years ahead of the Franco revolt in Spain. The Cairo Congress of 1937 was held while Spain was still in the throes of fratricidal warfare.

Very successful gatherings occurred respectively in Washington in 1922 and in London in 1925. The former could not be completely international in its scope, because officially the United States was not yet at peace with Germany and Austria. It is not, however, accurate to state (as was done quite recently) that the Washington Congress was limited to English-speaking ophthalmologists. German could not be recognized, but the official languages of the Congress were English, French, and Spanish, and papers were read in all three. The Congress at London in 1925 was definitely a Congress of English-speaking ophthalmologists, and was very well attended.

After a good deal of discussion between the official representatives of different countries, it appears now that the sixteenth International Congress of Ophthalmology will be held in London, England, July 17 to 21, 1950. Apart from any startling complications in the international political situation, that Congress is likely to be attended by a large number of colleagues from the United States, and the making of necessary reservations will soon be proper matter for consideration.

During World War II, the impossibility of holding such Congresses in Europe led an energetic group of American ophthalmologists, north and south of the Equator, to plan for the organization of a Pan-American Congress of Ophthalmology. As a beginning, this was held after the conclusion of the meeting of the American Academy of Ophthalmology and Otolaryngology at Cleveland in 1940, the languages officially used in the program being Spanish, Portuguese, and English.

A second Pan-American Congress of Ophthalmology was planned for November, 1943, in Montevideo, Uruguay, but the travel difficulties arising from the War caused repeated postponements of this gathering, which was finally held in November, 1945. A third Pan-American Congress was very successfully staged in Havana in January, 1948, with a large attendance by ophthalmologists (and their families) from North, South, and Central America. The next, fourth, Pan-American Congress will be held in Mexico City in 1952.

Undoubtedly, under peaceful conditions, many ophthalmologists of the United States will attend both the London International Congress in 1950 and the Mexico Pan-American Congress in 1952, and both events should be kept in mind in making travel plans for the coming four years.

W. H. Crisp.

BASIC SCIENCE RESEARCH
IN OPHTHALMOLOGY

One of the encouraging features of postwar ophthalmology in the United States is the number and quality of basic science studies dealing with eye problems that have

been reported. A substantial proportion of these studies has been made by ophthalmologists but more have been made by nonophthalmologists working in university eye departments or institutes or in the basic science departments of the medical schools and universities.

The Association for Research in Ophthalmology, which is the only national ophthalmological society dealing primarily with experimental ophthalmology and offering membership on an equal basis to both ophthalmologists and nonophthalmological basic science workers, has recognized the importance of providing a common meeting ground for the ophthalmologist and the nonclinical investigator. At the 1948 meeting of the association, its constitution was amended to permit the formation of regional sections similar to those established by such other organizations as the Society of American Bacteriologists. Section secretaries have already been named and two sections—the Western Section whose secretary is Dr. Michael J. Hogan of San Francisco; the Eastern Section whose secretary is Dr. Alson E. Braley of New York—have already held section meetings.

The Western Section meeting was held on March 27, 1948, in San Francisco and was attended by about 75 ophthalmologists and nonophthalmological investigators from the various basic science departments of the western universities. The program included the presentation of five experimental studies, followed by a banquet and an address by Frank W. Weymouth, Ph.D., professor of physiology at Stanford University, entitled, "Recent measurements of the living eye and their relation to the development of myopia." A second meeting is to be held in San Francisco this month, immediately following the examinations of the American Board of Ophthalmology.

The first meeting of the Eastern Section was held in New York City on November 13, 1948. Four papers were presented, one by an ophthalmologist and the other three by basic science workers from Harvard University and Columbia University. About 100 persons attended the meeting.

The section meetings, as judged from these first two, will not be in competition with the annual meeting of the national association but on the contrary will, in the main, provide a forum for the presentation of preliminary reports, the more important of which may subsequently be developed for presentation at the national meeting. Perhaps the most important function of the sections will be to bring together on a regional basis all the clinical and nonclinical investigators interested in ophthalmic research. In this age of coöperative research it is only by a constant interchange of ideas, facilitated by personal contacts between workers, that we can hope to see the full development of basic science investigation.

Phillips Thygeson.

THE FOURTH ARGENTINE CONGRESS OF OPHTHALMOLOGY

The Argentine Congress of Ophthalmology, which is held every four years, had its fourth assembly December 13 through 18, 1948, at Mar Del Plata, Argentina. The officers this year were: President, Dr. Diego M. Argüello; vice-president, Dr. Roberto F. Pereira; secretary, Dr. Juan L. Giambruni; treasurer, Dr. Bruno Tosi.

Mar Del Plata, Argentina's most famous and fashionable summer resort, is located on the coast 250 miles south of Buenos Aires. The meeting was held in the modern, air-conditioned auditorium of the Casino, or Kursaal, and most of those attending the congress lived at the beautiful Hermitage Hotel just across the street from the Casino.

The entire week was devoted to the meeting. On Monday morning the formal inaugural ceremonies were held at which time a cordial welcome was extended by the president of the congress, by federal and municipal officers, and by the titular professors of ophthalmology at the various uni-

versities. Greetings were received from the official visitors. A scientific session was held each morning from 9 to 12 o'clock, and this was followed by a 4-hour interlude for lunch, siesta, and recreation. The afternoon sessions began at 4 o'clock and lasted until 7; the evenings were free for social gatherings.

The scientific program was arranged along the lines usually employed in Europe. Certain subjects were selected for discussion, and this congress was devoted primarily to "Tumors of the eye and adnexa." Two other official themes were "Surgery of the extraocular muscles" and "Prevention of blindness." In addition to these subjects there were miscellaneous papers and moving pictures on aspects running almost the entire gamut of ophthalmology. Fourteen instruction courses were given. These were excellently arranged and presented and were most enthusiastically received.

In the spacious anterooms adjoining the auditorium there were scientific and commercial exhibits. The scientific exhibits were particularly meritorious. These were sponsored by the various universities instead of by individuals. There were exhibits from the Universities of Buenos Aires, La Plata, Cordoba, and Litoral. In addition, the government agencies, such as the Secretary of Public Health and the Secretary of Education, had comprehensive exhibits demonstrating the efforts they are making along lines related to ophthalmology and projecting their plans for the future.

There were the usual commercial exhibits, not only of Argentine firms, but also those of various foreign nations. Of particular interest was the wide variety of publications on display: the latest ophthalmological books of English, French, Swiss, German, Italian, and American authors were exhibited. Argentine manufacturers had on display their own model of a slitlamp, ophthalmometer, refractometer, ophthalmoscope, and so forth, as well as various surgical instruments.

The meeting had a strong international flavor due to the presence of many foreigners, including leading ophthalmologists of Europe and the other South American countries. Eminent visitors from Europe were Franceschetti of Switzerland, Arruga of Spain, Barraquer of Spain, and Velter of France. Alvaro was the official delegate from Brazil and the United States. Castroviejo and Hanson from the United States attended and participated in the program.

Argentine ophthalmologists are very versatile. In their number they include an international playwright, Dr. Carlos S. Damel, and an olympic fencer, Dr. Jorge Balza. They are all surprisingly good linguists. Most of them speak English, but all seem to have a knowledge of at least one language other than Spanish. They are amazingly indulgent of a foreigner's efforts to speak their language.

It was early summer in the Argentine, when the Congress was held, and the weather lent itself to recreation and social activities which were a delightful feature of the meeting. The beach was readily accessible to the hotel and, in addition, golf and other sports were available. The Casino, a tremendous recreational center operated by the government, has the largest gambling facilities in the world.

The impromptu gatherings for lunch and dinner were diverting and stimulating. Since on Wednesday afternoon there was no scientific session, a barbecue was held at a large private estancia in the pampas. After lunch some Argentine cowboys, or gauchos, demonstrated their horsemanship. Later in the afternoon a visit was made to another ranch where race horses and polo ponies are bred. A number of former Derby winners were exhibited.

The congress was concluded on Saturday evening by a most delightful banquet at which there were after-dinner speeches by the representatives of the various countries.

To me it was a great privilege and pleasure to attend this meeting. The scientific program was excellent; the subjects for dis-

cussion were many and varied; the presentations were well done; discussions were spirited but always tolerant. The Argentine people are extremely hospitable and friendly, and have the happy faculty of combining their serious scientific endeavors with the light touch of pleasure and conviviality.

I departed with a great affection for the Argentine ophthalmologists and a great respect for their ophthalmology.

Algernon B. Reese.

BOOK REVIEWS

DETAILED ATLAS OF THE HEAD AND NECK. By R. C. Truex and C. E. Kellner. New York, Oxford University Press, 1948. 135 pages, 136 colored plates, index. Price, $15.00.

We have waited a long time for an atlas like this. It vividly recalls the famous anatomic atlas of Johannes Sabotta and J. Playfair McMurrich, long out of print and a collector's item. Dr. Truex, associate professor of anatomy, and Mr. Kellner, artist, Department of Anatomy, College of Physicians and Surgeons, Columbia University, have worked, in the words of Professor Detwiler in his foreword, "diligently and untiringly on this atlas, and in a state of true symbiosis!"

The beauty of the plates and the concise, accurate descriptions that accompany them cannot be improved upon. Figures 1 to 82 detail the regional anatomy; Figures 83 to 104, the skeletal structures; Figures 105-116 are representations of frontal sections; and Figures 117 to 136 are those of transverse sections.

The anatomy of the globe, the orbit, and the adjacent structures are clearly displayed, better perhaps than if the actual injected specimens were in a tray in front of you. Those who are sensitive to formaldehyde had better take care, for the pictures are so true that an allergic response could result, if our friends the psychosomatic experts are correct.

The publishers deserve enormous credit for their splendid job. Not a single ophthalmologist should be without his own private copy.

Derrick Vail.

THE W. H. ROSS FOUNDATION (SCOTLAND) FOR THE STUDY OF THE PREVENTION OF BLINDNESS. Reprinted Papers. London, University of London Press, Ltd., 1948. Paper binding, 232 pages, appendix with statistical tables. Price, 3 shillings.

The Ross Foundation is an organization of the broadest scope with a full-time research ophthalmologist as director. The present volume contains the history of this great undertaking and a report on the research sponsored to date. All the technical papers have been published in various professional journals as selected by the individual investigator. The AMERICAN JOURNAL OF OPHTHALMOLOGY was the choice for the significant paper on ocular siderosis by Loewenstein and Foster.

William Henry Ross, a self-made man of great wealth, established the Foundation in 1935 after becoming sightless. He lived until 1944 and was impressed by the continuous achievements of his philanthropy. The Foundation popularized sodium sulfacetamide, first for counteracting infections of the eye following mustard gas, next for the better control of corneal ulcers. The treatment recommended was direct application of the powder to the ulcer followed by after-instillations of sulfacetamide solution. The sulfacetamide penetrated readily into the cornea, much more than sodium sulfadiazene, did not produce deleterious irritation, and its local use resulted in a much greater concentration in the ocular tissues than was attainable by systemic sulfonamide therapy. The intravitreal injection of pure penicillin was found highly effective in preventing panophthalmitis experimentally. The drug diffuses so slowly from the vitreous that an adequate concentration is maintained for 2 to 3 days.

The industrial studies showed that fluorescent lighting lost 50 percent of its effectiveness in 18-months' time. In the schools a careful comparison of reading age with mental age revealed dyslexia in some degree in 11.5 percent of boys and 7.4 percent of girls. The Foundation is now assembling records of blindness in one eye for their great value in the study of prevention. Cannot a similar survey be made in this country?

James E. Lebensohn.

ESSENTIALS OF PATHOLOGY. By L. W. Smith and E. S. Gault, with a foreword by the late James Ewing. Philadelphia, The Blakiston Company, 1948, Edition 3. 764 pages, 740 illustrations, a number in color; bibliography, index. Price, $12.00.

The busy ophthalmologist, immersed in the minute aspects of his field of activity, is in constant danger of forgetting that he is primarily a physician. There are times when he longs for the opportunity to renew his student days and to recall his absorption in the basic studies of medicine. Alas, not many of us have the time or energy to read textbooks of general medical subjects, along with our specialized reading.

One of America's great ophthalmologists of an older vintage, when catch-as-catch-can training was all that was available, had for his personal program of self-instruction a schedule of reading every night for five nights a week, divided into three one-hour periods. The first was given to ophthalmology, the second to general medicine, and the third to the world's great English literature. He faithfully pursued this schedule throughout his happy life. He was an educated man.

Ophthalmologists who wish to recapture their medical soul will take pleasure in owning and reading Smith and Gault's well-known Essentials of Pathology, particularly in this beautiful new and completely revised edition. They will find, on nearly every page, information that is pertinent to ophthalmology and of use to them in their daily work.

For example, to pick some chapters at random, there is a splendid discussion of retrograde processes, another on disturbances of circulation, an excellent description of the avitaminoses, another of inflammation, and, particularly important in these days of a wide-open world, new information on animal parasites. These authors have taken great pains to illustrate their text liberally and most satisfactorily.

Apparently every system of the body is well covered, except the eye. This is deplorable, because general physicians and pathologists are entirely ignorant of ocular pathology. A chapter on this subject would complete a fine piece of work.

Derrick Vail.

TRANSACTIONS OF THE OPHTHALMOLOGICAL SOCIETY OF PARIS (and of the Ophthalmological Societies of the East, of Lyon, and of the West). Meeting of March, 1948, pp. 83-102.

Deschamps presents a man, aged 58 years, with all the signs and symptoms of an orbital neoplasm. Exact diagnosis of a mucocele of the frontal sinus was made only after orbitotomy. Recovery was uneventful, motility improved slowly, and the exophthalmos disappeared. Vision was restored. There was only a mild disturbance in the function of the superior oblique muscle. The disc remained pale with some blurring of its margin.

In a study of corneal nerves, Offret found that the staining methods of Cajal were unsatisfactory but that modification of Ranvier's technique was effective. Flat sections and radial incisions gave good exposure. A few Schwann's elements were easily seen.

Guillaumat and Lemaitre observed myopia gravis, retinitis pigmentosa, and congenital luxation of the lenses in a young woman whose parents were first cousins. The patient's general health was good. She

had four normal children, but each pregnancy had caused an increased loss of vision. Although the authors believe that the disease is essentially hereditary, they also suspect that the influence of hormonal factors may have caused the visual impairment after each delivery.

Sédan and Sédan-Bauby discuss micropuncture as a means of testing the resistance of the lens capsule. They comment on the older experiments of Czillag which had only recently become known to them. The authors, themselves, use a needle puncture of the lens capsule in vivo.

Larmande describes calcified and ossified angiomas of the choroid. Choroidal angiomatosis can cause calcium precipitation in the vessel walls of the lesion and its immediate neighborhood, even in the retina. These pathologic processes might be seen combined in a symptom complex which the author calls encephalofacial neurangiomatosis.

Hartmann describes an atypical case of suprasellar meningioma with unilateral dilatation of the optic canal. A woman, aged 49 years, had temporal hemianopia in the right eye with temporal pallor of the disc. The left eye was normal. Exact diagnosis was made only during surgery.

Alice R. Deutsch.

SOME ASPECTS OF OCULO-REFRACTIVE TECHNIQUE. By Malcolm Cholerton. London, Hammond, Hammond, & Co., Ltd., 1948. Clothbound, 147 pages, 23 figures, index and bibliography. Price, 21 shillings.

The author, a British ophthalmic optician (equivalent to the American optometrist), is concerned with the professional preparation of his colleagues, and this book aims to broaden their acquaintance with visual functions. His very readable digest is based on the works of Duke-Elder, Parsons, Traquair, Chavasse, and Luckiesh, supplemented by selected articles from the journals of ophthalmology, all of which are duly credited. Mr. Cholerton, who worked in the war with British and American ophthalmologists, maintains throughout a correct professional attitude. Scorning practitioners who prescribe base-in prisms for migraine, he states, "In view of the incidence, not infrequently, of migraine associated with pathological disturbances such as cerebral aneurysm or tumor, the patient should be referred for ophthalmological and neurological investigation."

His discussion on dynamic retinoscopy opens with this opinion: "In its present state of development as a technique it is based upon certain assumptions, the validity of which are still questionable." As regards tinted lenses, "The aim should be to remove or diminish the patient's conviction that a tint must be incorporated as a necessary part for the solution of his ocular disability."

The optical data submitted is at times insufficiently explicit. He suggests the use of a trial-case telescope, made by placing plus 20D. and minus 20D. lenses in the front and back cells respectively, but does not mention that this combination only functions at a distance of 10 inches. This slim volume no doubt will be of value to the group for whom it was written.

James E. Lebensohn.

ABSTRACT DEPARTMENT

EDITED BY DR. F. HERBERT HAESSLER

Abstracts are classified under the divisions listed below. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

1. Anatomy, embryology, and comparative ophthalmology
2. General pathology, bacteriology, immunology
3. Vegetative physiology, biochemistry, pharmacology, toxicology
4. Physiologic optics, refraction, color vision
5. Diagnosis and therapy
6. Ocular motility
7. Conjunctiva, cornea, sclera
8. Uvea, sympathetic disease, aqueous
9. Glaucoma and ocular tension

10. Crystalline lens
11. Retina and vitreous
12. Optic nerve and chiasm
13. Neuro-ophthalmology
14. Eyeball, orbit, sinuses
15. Eyelids, lacrimal apparatus
16. Tumors
17. Injuries
18. Systemic disease and parasites
19. Congenital deformities, heredity
20. Hygiene, sociology, education, and history

1

ANATOMY, EMBRYOLOGY, AND COMPARATIVE OPHTHALMOLOGY

v. Bahr, Gunnar. **Measurements of the thickness of the cornea.** Acta ophth. 26: 247-266, 1948.

The literature on this subject is reviewed and a new instrument for this purpose used in conjunction with the Gullstrand slitlamp is described in detail. The mathematical formula used to calculate the corneal thickness is explained. Normal eyes of 125 persons of both sexes and different ages were examined. The effect of hypertonic and hypotonic solutions on the corneal thickness was tested on rabbit and human eyes. The average thickness of the cornea is 0.565 mm. and varies between 0.46 and 0.67 mm. The cornea in eyes with myopia over four diopters was thinner. Changes in the corneal thickness of rabbits were produced experimentally by baths in solutions of unphysiological osmotic pressure. The thickness is increased by baths of 0.5-percent sodium chloride, and decreased by baths of a 2-percent solution.

Ray K. Daily.

Fornes Peris, Enrique. **The comparative morphology of the corneal fibrocytes.** Arch. Soc. oftal. hispano-am. 8:821-826, Aug., 1948.

This is a detailed report on an investigation of the cornea of man, the rabbit, pig, bull, chicken, lamb, frog, cat, snake, and mullet with the Llombart silver stain method. All the corneal cells are fibrocytes. No histiocytes or leucocytes were encountered. Fibrocytes are irregular elements which under normal conditions are fixed or but slightly movable. They have an abundant cytoplasm which adapts itself to the form of the cell, and flattened anastomizing prolongations. The cells have two predominant forms, membranous as in man, and corpuscular as in the chicken. The cellular elements are abundant in all the corneas investigated; they have numerous prolongations, short in some cells, thin in others, and some cells have both types. The union of these processes forms a true syncitium, best demonstrated in the cornea of man and the hog.

The characteristic form and volume of the cell, the position of its expansions,

the manner of the anastomosis of the fibrocytes varies in different animals. The distribution of the cells in the connective tissue is quite regular in the chicken and complicated in man. The cellular expansions may be filiform, or may originate in a broad base and become narrow at the end; some are smooth and uniform in size throughout their entire extent, while others are bristly with spines, and irregular in size. The cornea of the hog is very similar to that of man and that of the cat less so. The fibrocytes of the hog, and to a lesser extent those of the cat, are similar to those of man in their unequal distribution, in the broad form of their extensions, and in the arrangement in broad layers. Ray K. Daily.

Meves, H. **The structure of the retinal arteries.** Arch. f. Ophth. 148:459-467, 1948.

The tissues of 16 eyes of young persons were embedded in paraffine and stained with Weigert's elastica lithium carmine. Whereas the central artery near the lamina cribrosa shows a single layered internal elastic membrane just beneath the intima, the retinal branches present at least 3 or 4 elastic membranes. The membranes are concentrically arranged and interrupted by numbers of smooth muscle cells. The difference between the retinal arteries and the choroidal vessels of the muscular type is emphasized.
Ernst Schmerl.

Scobee, R. G. **The fascia of the orbit. Its anatomy and clinical significance.** Am. J. Ophth. 31:1539-1552, Dec., 1948. (9 figures, 15 references.)

2

GENERAL PATHOLOGY, BACTERIOLOGY, IMMUNOLOGY

Fischer, F. P. **The frequency curves of senile ocular changes.** Ophthalmologica 116:6-9, July, 1948.

In 1941 (Ophthalmologica 106:226) the author reported on the incidence in the various age groups of typical senile changes in man, such as arcus senilis, depigmentation of the iris and acquired cataract. The frequency distribution of these three characteristics of senescence was expressed by S-shaped (Sigmoid) curves (plotting incidence on the ordinate and age on the abscissa). The relationship between the logarithm of the frequency to the logarithm of age was expressed by a straight line except for the extremely high values. In the paper under review Fischer stresses the mathematical difference between growth curves and senescence curves (see the author's contribution on "senescence of the eye in Sorsby's Modern Trends in Ophthalmology, Vol. 2). Peter C. Kronfeld.

Joy, H. H. **Uveopigmentary sensitization.** Am. J. Ophth. 31:1581-1588, Dec., 1948. (54 references.)

Knecht, F. **The influence of climatic conditions upon the non-acute glaucomas.** Ophthalmologica 116:21-37, July, 1948.

This study was made in the department of ophthalmology of the University of Basle (Switzerland) which is suitably located for investigations of the influence of meteorological factors upon the development and course of diseases. In that locality A. Brueckner demonstrated a relationship between the weather and the onset of acute glaucomas. (See Archives of Ophthalmology 20:950, 1938.)

In the paper under review the non-acute glaucomas were classified as simple, chronic (characterized by recurrent mild attacks), secondary, absolute or hemorrhagic forms. More cases of non-acute glaucoma registered as new patients during the winter than during the summer of the years from 1936 to 1945. January and March represented the

maxima and August the minimum of the seasonal distribution curve. Close observation of the diurnal variations of ocular tension revealed a surprisingly high incidence of elevations that could be correlated with cold waves, heat waves or other sudden meteorologic disturbances.

Peter C. Kronfeld.

Rapisarda, Dante. **Conjunctival tuberculous hetero-allergy. Part II: histologic study.** Ann. di ottal. e clin. ocul. 73:344-371, June, 1947.

Part I of this study was reported during the 36th Congress of the Italian Ophthalmological Society. Rabbits and guinea pigs were sensitized by injections of vaccines and of live bacilli of low virulence, and subsequently tests were made to determine the reactivity of the conjunctiva to instillation and subconjunctival injection of tuberculin and nonspecific stimuli (milk and gonococcus vaccine). In all cases the conjunctival reaction was more marked in the sensitized animals than in the controls, and nonspecific stimuli incapable of producing any reaction in normal animals produced intense and lasting reactions in the sensitized animals. This augmented reactivity (hetero-allergy) of tuberculin-sensitized animals to nonspecific stimuli may give a clue to the treatment of certain recurrent and intractable forms of conjunctivitis, and Rapisarda is carrying on further studies. The reactive process was studied histologically in its several phases. Three stages were distinguished, an exudative, a granulomatous, and a sclerotic. (8 figures, references.)

Harry K. Messenger.

Redi, Francesco. **Localized amyloidosis, with particular attention to conjunctival amyloidosis, in the picture of paraamyloidosis and their etiologic relationships.** Giorn. ital. di oftal. 1:227-264, May-June, 1948.

Paramyloidosis, in its localized and circumscribed form, must be considered separately from amyloidosis, differentiated by the history, histologic aspects, and finally by the microchemical reaction. The differentiation is illustrated by a case of paramyloidosis of the myocardium, and one case of paramyloidosis of the conjunctiva. Experimental amyloidosis in the white mouse has all the characteristics of human generalized amyloidosis and not of paramyloidosis. In the course of chronic cavitating tuberculosis degenerative histologic changes are not found in the lids or conjunctiva nor are the infiltrative changes usually thought to be preamyloidosis changes. In the course of trachoma one does not find amyloid changes of the lids or even of the conjunctiva. Mechanical stimuli repeated many times have not given rise to degenerative substances in normal animals nor in animals treated with sodium caseinate. Trementine injected into the area of the lids of guinea pigs causes the amyloid substance to disappear in normal animals and in those treated with sodium caseinate. The experiments indicated that disturbances in metabolism have not influenced the pathogenic mechanism of localized amyloidosis, rather that local conditions are responsible factors.

Francis P. Guida.

Spyratos, S. P. **Promelanine.** Ann. d'ocul. 181:556-565, Sept., 1948.

This nucleoprotein is an inductor for undifferentiated embryonic cells. In the secondary optic vesicle promelanine aids in the formation and differentiation of retinal and choroidal pigmentation. It transforms some cells of the periocular mesenchyme into melanoblasts. Melanophores of the eye and skin are apparently related. After birth, under some environmental conditions largely unknown, promelanine granules may transmit the tendency to specific types of inflamma-

tory reactions to other mesoblastic tissues. Sympathetic ophthalmia is thought to be a reaction of this type which involves primarily mesoblastic pigmentation in the uvea of both eyes.   Chas. A. Bahn.

Albright, A. A., and Seretan, E. L. Sulfathiazole sensitivity: with a review of the literature. Am. J. Ophth. 31:1603-1606, Dec., 1948. (18 references.)

Bárány, E. H. The influence of gum arabic and dextran on the blood-aqueous barrier and intraocular pressure. Ophthalmologica 116:65-79, Aug. 1948.

Dieter and Duke-Elder reported marked lowering of the ocular tension after intravenous injections of concentrated solutions of gum arabic into rabbits. Both authors interpreted these lowerings as manifestations of the great influence of the colloid-osmotic pressure of the blood on the ocular tension. Closer analysis of these experiments reveals a striking absence of parallelism between the rise in the colloid-osmotic pressure of the blood on the one hand and the drop of ocular tension on the other hand. Bárány repeated these experiments with gum arabic solutions of varying concentration and confirmed the findings of Dieter and Duke-Elder. Following the injections he measured the ocular tension and, by means of the colloidometer of Roenne, the intensity of the aqueous flare. A striking parallelism between the colloid content of the aqueous and the drop in ocular tension became apparent. Both phenomena were also found to occur after the intravenous injection of gum arabic solutions of lower osmotic concentration than plasma. The same effects could be obtained with dilute solution of

dextran which is a polysaccharide used in Sweden as a plasma substitute. In its natural form dextran has a molecular weight of many millions. By hydrolysis the molecule can be broken down to particles of a molecular weight of less than 200,000. The natural substance in dilute solution produced a drop in ocular tension with marked aqueous flare, while equivalent amounts of the hydrolysate were ineffective. These observations show that the hypotony after the intravenous injection of high-molecular colloids is not caused directly by osmotic factors. "When hypotony occurs it is always associated with colloid increase in the aqueous, signalling a breakdown of the blood-aqueous barrier. Injury to the barrier is probably a causal factor in the production of hypotony by these substances (gum arabic and dextran)."

Boros, B., and Vönöczky, J. Penetration of sulfonamides into the eye. Ophthalmologica 116:177-186, Sept., 1948.

The penetration into the eye of systematically applied sulfonamides was studied in cats. Topically applied pilocarpine, atropine or adrenaline did not significantly alter the rate of sulfonamide penetration. Gynergen and bacterial inflammation raised the intraocular sulfonamide concentration significantly. After single intravenous doses of 3 to 4 grams of sulfonamides adequate sulfonamide levels were found in the vitreous of a few human eyes which had to be enucleated because of endophthalmitis or absolute glaucoma. The ineffectiveness of sulfonamides in many types of intraocular infection should not be attributed to low intraocular sulfonamide levels.

De Vincentiis, M. The oxidation activity of the human cataract in the pres-

ence of amino acids. Rassegna ital. d'ottal. 17:247-253, July-Aug., 1948.

The author studied the respiratory behavior of the cataractous human lens in the presence of amino acids. He established the fact that cystine, asparagine and tyrosine were increased and that glycocol, leucine and histidine were diminished in amount. He also observed a diminution of alanine and tryptophane. The changes established the fact that all respiratory activity of the lens disappears from the opaque lens fibers.

Duke-Elder, S., and Davson, H. The present position of the problem of the intra-ocular fluid and pressure. Brit. J. Ophth. 32:555-569, Sept., 1948.

For many years it has been accepted as fact that the aqueous is an ultrafiltrate of the plasma, a dialysate which moves directly through the capillaries of the ciliary body into the anterior chamber by simple osmosis. If this were true this dialysate should be in dynamic equilibrium with the plasma. This theory fails to explain some of the data. The concentration of the electrolytes sodium and chloride in the aqueous is consistently higher than in the blood stream. It has been suggested that these substances were involved in metabolism of the lens, but since the same imbalance holds in the aphakic eye there must be some other explanation. The concentrations of carbohydrates in the aqueous of the normal and aphakic eye are much lower than in the blood and that complicates the problem further.

Nitrogenous substances, especially urea, are also present in lower concentration in the aqueous. Factors other than those of simple osmosis must be at work. As an alternative theory, the authors suggest that aqueous is actually elaborated entirely within the cells of the ciliary body and is drained away too quickly to be altered by osmosis with the plasma.   Morris Kaplan.

Ferguson, W. T. W. Ocular disturbances associated with malnutrition. Tr. Ophth. Soc. U. Kingdom 66:108-109, 1946.

The author reports on the ocular manifestations of volunteers whose diet was deprived of vitamin A in one experiment, and of vitamin C in another, conducted for the Medical Research Council in Sheffield. The two best criteria for assessing the course of the depletion of vitamin A were the vitamin A and carotenoid content of the blood plasma, and the capacity for dark adaptation.

There was a rapid drop in the carotenoid content of the blood in three months. The average value fell from an initial 150 i.u. per 100 ml. of plasma to 12 or 40. There was a distinct correlation between the vitamin A level in the blood plasma and the capacity for dark adaptation. The latter was normal if this level was about 50 i.u. per 100 ml. In only three subjects was this level reached after a period of 25 months. No changes were found in the degree of opacity in the conjunctiva that were not found also in the controls and a few small aneurysmal dilatations of the limbal vessels were also noted in the controls.

The depletion of the diet in vitamin C caused no change in the capacity for dark adaptation and no changes were visible with the corneal microscope.

Gandolfi, C. The action of Priscol on the retinal arterial pressure. Ann. di ottal. e clin. ocul. 73:336-343, June, 1947.

Priscol "Ciba" is 2-benzylimidazoline hydrochloride, a new peripherally acting vasodilator. Conjunctival instillation of Priscol in man had no effect on the

retinal arterial pressure as measured with Baillart's ophthalmodynamometer. The intramuscular injection of 1 cc. of a 1-percent solution caused only a slight and inconstant reduction, but a retrobulbar injection of the same quantity caused a rapid, definite, and prolonged reduction of the retinal arterial pressure. The injection did not affect the systemic blood pressure and made no significant alterations in the intraocular pressure.

Harry K. Messenger.

Gandolfi, C. **A new drug for surface anesthesia in ophthalmology.** Ann. di ottal. e clin. ocul. 73:439-441, July, 1947.

A ½-percent solution of Butococaine, a butyn-like product of the Zambelletti laboratories, was found on clinical trial to meet all the requirements for satisfactory surface anesthesia. An instillation of a single drop produced in one minute complete corneal anesthesia which lasted ten minutes. There was no mydriasis or desquamation of the corneal epithelium, and the pupillary reactions and the ocular tension were not altered. No intolerance was noted in several hundred patients. Solutions may be sterilized by boiling. The slight hyperemia which follows the instillation may be prevented by the addition of epinephrine solution.

Jones, I. H., Muckleston, H. S., Lewis, E. R., and Owens, G. R. **Nutrition in ophthalmology and otolaryngology.** Ann. West. Med. and Surg. 2:491-499, Nov., 1948.

The authors emphasize the embryological view of nutrition in that the germ layers have specific vitamin requirements. Rats on controlled diets were perfused and the microscopic tissue studies are reported. In dietary deficiencies the cells were found to be shrunken, many absent. When the animals were given complete diets the tissues rapidly returned to normal. Orwyn H. Ellis.

Kapuscinski, W. **On symptoms of the pulse in the central retinal artery.** Brit. J. Ophth. 32:881-885, Dec., 1948.

Direct examination of the fundus shows two kinds of pulse, one spontaneous and the other artificial, from pressure on the eyeball. The author has observed that when pressure is made on the eyeball the first movement is a sagging of the walls of the artery which is synchronous with the cardiac systole. If the pressure on the eyeball is increased then the rhythm of the arterial pulse becomes alternate. There is then a dilatation in the retinal artery simultaneously with the cardiac systole, and a contraction of that artery with diastole. The latter is the phenomenon which should be interpreted according to Graefe's theory.

Knape, Birgitta. **Studies on the effect of certain stimulants on the accommodation of the eye and of the threshold value for the effect of vitamin B₁ on the accommodation.** Acta ophth. 26:35-40, 1948.

Accommodation was tested by the Vannas method for each eye separately immediately before the administration of the stimulant, directly after, and at intervals of varying length. The effect of the oral administration of pervitin was tested in 20 persons, of intramuscular injections of coramin in 6, of caffein in 10, and of intravenous injections of vitamin B_1 in 64. The charted data show that the maximum effect, a 5-percent increase in accommodation for pervitin, occurs after 1½ to 2 hours, and accommodation falls below the initial strength after 2½ hours. The maximum effect, a 5-percent increase in accommodation, occurs almost immediately after the injection of coramin, and there is no subsequent depres-

sion. The tests for vitamin B_1 were controlled with injections of physiologic saline solution, which had no effect on accommodation. The threshold value for the effect of vitamin B_1, to which accommodation appears to be very sensitive, is between 2 and 5 mg. Half an hour after the intravenous injection of 5 mg. of vitamin B_1 accommodation is increased 6.1 percent, and the effect lasts about 24 hours; the effect of smaller doses is less marked and of shorter duration.

Neujean, G., Weyts, E., and Bacq, Z. M. Action of B.A.L. on ophthalmologic accidents resulting from treatment with tryparsamide. Bull. Acad. roy. de méd. de Belgique 13:341-350, 1948.

Eye complications during treatment of trypanosomiasis with tryparsamide are frequent. Observations made on negroes at the Institure for Tropical Medicine at Léopoldville, in whom the trypanosomiasis had attacked the central nervous system and who had been treated with tryparsamide, showed the efficacy of B.A.L. in combating visual complications. This action, though never spectacular, is often, but not invariably, favorable, even when the trouble has been of long standing, and when no improvement can be seen ophthalmoscopically in the lesions of the optic nerve. B.A.L. hinders the therapeutic value of the tryparsamide. The authors demonstrate this action by means of a chemical equation. Nine detailed case histories are given. (6 references.) B. T. Haessler.

Palm, Erik. The phosphate exchange between the blood and the eye. Acta ophth. Suppl. 32, pp. 1-114, 1948.

The objective of the present investigation was to follow the passage of the radioactive isotope of phosphorus, 32 P in its transit from the blood through the anterior uvea and aqueous to the lens; it was hoped that the findings might throw some light on some of the as yet unknown processes of the eye, such as the formation of aqueous and the metabolism of the lens. The use of an isotope of a substance which normally occurs in the body, in the study of vital processes, permits the making of investigations under undisturbed physiologic conditions; the data of former investigations are vitiated by the error in the results caused by an interference in these processes by the introduction of substances foreign to the organism, such as dyes, or by a disturbance in the osmotic balance through the use of abnormally high concentrations of substances nor-

mally occurring in the body. The chemistry of the phosphorus compounds that take part in the metabolism of the eye is reviewed, the experimental arrangement for the present investigation described in detail, and the results are tabulated and presented graphically. The experiments were done on living rabbits and on isolated lenses in vitro. Labeled phosphate in negligible amounts was injected intraperitoneally in rabbits, and its concentration in the blood determined at various intervals. At different times the animals were killed, their eyes extirpated, and the aqueous humor, vitreous body, anterior uvea, lens and cornea removed for chemical analysis, which revealed to what extent the phosphate in the various fractions had been replaced by the newly administered phosphate. The experiments on isolated lenses were performed by placing the lenses in a labeled phosphate bath the composition of which approximated that of aqueous. At different intervals the amount of this phosphate in the lens was determined by radioautographs. The radioactive substance darkens a photographic film and provides a rough picture of the distribution of the newly added phosphate in the lens. At the conclusion of the experiment the phosphate content was determined by trichloracetic acid extracts. The anterior and posterior lens surfaces were tested separately to determine the difference in the metabolism The data show that a short time after the intraperitoneal injection the newly introduced molecules are found inside the lens and are distributed along the path of transport to it. The slowest exchange takes place between the blood and the anterior uvea. Apparently there is a barrier to the permeability in that area. Determinations of the organic phosphate in the uvea reveal that approximately all phosphate passing through the uvea undergoes a transitory organic phase; this metabolism in the uvea lends support

to the secretory theory of the formation of aqueous. The concentration of the labeled substance is almost the same in the uvea, the aqueous, and in parts of the organic and inorganic phosphate of the lens. The variations in the phosphate content of the anterior uvea and the aqueous follow one another closely, indicating a rapid exchange between the anterior uvea and the aqueous. The author suggests that this agreement indicates that the phosphate has a similar function in these tissues, perhaps as a carrier for a flow of carbohydrates from the blood to the lens. In the lens the newly introduced phosphate is rapidly converted into an organic form. Experiments on isolated lenses indicate that the metabolisms are different in the epithelium and in the substance of the lens. The material penetrates into the lens from the experimental bath through both the anterior and posterior surfaces with about equal intensity. An esterification of the labeled phosphate takes place at both surfaces, and the newly formed hydrolysable phosphate compounds appear in about the same proportion at both surfaces. The phosphate fraction remaining after hydrolysis for seven minutes is found only at the anterior surface of the lens. Since this fraction, which contains the first compounds of phosphorylation of carbohydrates, is found only at the anterior surface of the lens, it seems probable that such a process is associated with the epithelium of the lens, perhaps in connection with an absorptive activity.

Remler, O. Examinations in blind people with regard to the 24 hour rhythm. Klin. Monatsbl. f. Augenh. 113: 116-137, 1948.

Th vegetative functions of the body which include temperature, ocular tension, metabolism, digestion, and the activities of the renal, the cardiovascular

and the central nervous system are subject to a 24-hour rhythm. Excretion of urine, for instance, normally has its peak in the morning, the temperature in the late afternoon. The author examined 75 blind persons, eight of whom had been blind since early childhood, in regard to the behavior of the rhythm of their vegetative functions. There was relative similarity in behavior of temperature curve, pulse, blood pressure and urine excretion. Whenever the temperature curve was normokymatic, the others were normokymatic, too. Whenever the temperature curve was inverse, the other functions usually behaved in an inverse manner. One half of the persons who became blind later in life, as well the eight who were blind early had a normal pattern of 24-hour rhythm. This group comprised mostly people who were psychologically of the cyclothymic type and were mentally well adjusted. The greater number of the other half exhibited an inverse type of rhythm. A few showed a dyskymatic curve without any special characteristic feature. Most of the men in this latter group were psychologically of the schizothymic type, which comprises the introverts, the neurotics and those living under tension. Remler points to the normal behavior of rhythm in those who became blind early as proof that the day and night change has no influence on the establishment of such rhythm, and that rhythm is of endogenous origin. He believes that the inverted rhythm in the schizothymic types is a reaction to the new sightless environment and is influenced by the mental attitude. (References.) Max Hirschfelder.

Røe, Oluf. The ganglion cells of the retina in cases of methanol poisoning in human beings and experimental animals. Acta ophth. 26:169-182, 1948.

In a clinical study reported by the author in 1946, he showed that severe acidosis is necessary for the development of amblyopia and amaurosis. Experimental work on rats failed to find any acidosis in poisoned animals. He now reports the histologic examination of 12 eyes enucleated from patients who had died of methanol poisoning and of 21 rats and rabbits killed with methanol. The human retina shows severe degenerative changes in the ganglion cells. These changes did not develop in the experimental animals. A comparison of the clinical and experimental findings thus shows that there is a fundamental difference in the action of methanol on animals and human beings. Because of the failure to verify the significance of acidosis in animals, its importance to human beings was not recognized, and the failure to treat it resulted in unnecessary loss of life and sight. Ray K. Daily.

Sorsby, A., and Ungar, J. Distribution of penicillin in the eye after injections of 1,000,000 units by the subconjunctival, retrobulbar and intramuscular routes. Brit. J. Ophth. 32:864-873, Dec., 1948.

The authors review the literature and point out that adequate intraocular therapeutic levels have been obtained with subconjunctival penicillin injections, and that higher levels can be obtained when adrenalin is used as a diluent. In the present experiments adequate therapeutic levels were obtained for 48 hours after one injection. The levels obtained with retrobulbar injection, although considerable, are distinctly lower than those obtained by subconjunctival, and the levels from intramuscular injection are lower still. Massive systemic doses showed adequate therapeutic levels intraocularly. Orwyn H. Ellis.

Vannini, A. The influence of vitamin B_1 upon corneal anesthesia. Rassegna ital. d'ottal. 17:197-205, May-June, 1948.

Experiments were conducted upon human and rabbit eyes to determine whether vitamin B_1 has any influence upon the induction of anesthesia of the cornea. The vitamin was used in solution, the tonicity of which was less, greater than, or equal to that of the aqueous. No evidence of production of anesthesia could be determined. The use of cocaine upon one cornea and cocaine plus thiamine solution in the other eye resulted in lessened anesthesia from the latter. The same was true of novocaine and other local anesthetics. Experiments upon rabbits seemed to suggest that the vitamins aid in the process of regeneration of nerve fibers.

PHYSIOLOGIC OPTICS, REFRACTION, COLOR VISION

Bailliart, P. Reflections on the theories of vision. Ann. d'ocul. 181:514-534, Sept., 1948.

This contribution deals with a series of subjects which are suggested in a program for ophthalmic investigation. The first includes the specific photochemical and electrical reactions which transform light into sight, especially in the retina. Little is known of the details involved in the chemical composition or action of rhodopsin and its allied substances, the functions of the rods and cones, and the intercommunicating fibers of the retina. The relative differences in the perceptive powers of the nasal and temporal retina as well as their respective involvement in diseases such as glaucoma are also fruitful fields for investigation. The same is true of the shadows formed on the neuroepithelium by the retinal and choroidal vessels, and the complex subject of color vision. For those interested in ophthalmic problems this contribution has much of interest.

Chas. A. Bahn.

Beach, S. J. Verified refraction. J.A.M.A. 138:952-954, Nov. 27, 1948.

A refraction routine is described in which several methods of testing are used so that the results of one verify those of another. It is as simple as is possible without a sacrifice of accuracy. The history and visual acuity are taken first. A pinhole disc is next used. A preliminary noncycloplegic retinoscopy is performed and with the lenses in place, the fogging method of noncycloplegic examination is done. The use of the astigmatic dials is discussed here. The cross cylinders are then used. The vision is then corrected binocularly by the use of "cyclodamia" in which both eyes are unfogged gradually and equally. (When binocular vision is 6/60 the eyes are fogged by approximately +1.50 diopters, when the vision is 6/12 by about +0.50, and when the +0.50 D-lens is removed the 6/6 line should be read.) The near point of accommodation is then measured. Cycloplegia should be used routinely in young persons with active accommodation. The postcycloplegic examination follows the precycloplegic routine. The author recommends that the ophthalmologists learn to use these methods of refraction.

H. C. Weinberg.

Berger, A., and Monjé, M. The influence of aniseikonia upon depth-perception. Arch. f. Ophth. 148:515-528, 1948.

The authors place aniseikonic lenses in front of their eyes and study their own depth-perception with the help of the stereoeidometer. This instrument and its use have been described in a former article. When aniseikonic lenses were used which produced differences in size of the retinal images up to 17 percent, just a slight deterioration of the depth perception became noticeable. In another experiment adaptation to an artificially produced aniseikonia of 3.2 percent took place within an hour. Ernst Schmerl.

Bornschein, H. The avoidance of line voltage variations in adaptometry. Ophthalmologica 116:187-191, Sept., 1948.

The author who is engaged in exact adaptometry states his experiences with automatic devices intended to compensate for the usual and practically unavoidable line voltage variations.

Peter C. Kronfeld.

Boshoff, F. H., and Jockl, E. Errors of refraction and visual efficiency. Acta Med. Orient. 6:384-385, Dec., 1947.

Three cases of moderately high degree of myopia, one of them due to keratoconus are cited. All three patients were very proficient athletes, although they did not wear corrections for their refractive errors. One patient competed in the 1928 Olympic Games as a cricket player and was also an above average tennis player. The patient with the keratoconus was also an outstanding tennis player, and the third was an unusually good cricket player.

The authors believe the observations are worthy of record. They show that in the presence even of high degrees of uncorrected refractive errors precision performances, involving the handling of small fast-moving objects, can be carried out with a measure of efficiency exceeding that of fit healthy persons with normal refraction. Sharp definition of the retinal image can be only one of the factors which determine visual efficiency. The observations direct attention to the scope of effectiveness of the optical reception and interpretation fields in the brain and they demonstrate that athletic performances have a "total character," in which the visual functions involved become embedded in a comprehensive action pattern of the entire organism. Physical education can play an important part in ophthalmologic therapy, and the value of special eye exercises may be en-hanced by the systematic use of sport and general training.

Donald T. Hughson.

Broendstrup, Poul. The functional and anatomical differences between the nasal and temporal portions of the retina. Acta ophth. 26:351-362, 1948.

The difference between the nasal and temporal portions of the retina are reviewed and the author's own investigations to outline the anterior limits of the visual field by means of pressure phosphenes is reported. It was sought to determine whether the limits outlined by the phosphenes are identical with those charted perimetrically and campimetrically. The method consisted in making very slight pressure with a Bowman probe on the anesthetized eye. The pressure was made systematically, proceeding from the limbus backward in the horizontal, vertical, and two oblique meridians. The response to the pressure is a dark spot with a lighter center and a light halo. The distance between the limbus and the point of the most anteriorly possible phosphene was measured with a compass. Twelve persons, 8 of whom were emmetropic, were each examined twice. A visual phosphene field was constructed on the basis of the data thus obtained. Upward and downward the composite, constructed field practically coincides with the perimetrically measured visual field. Temporally, the field on the perimeter is more extensive, and on the nasal side the phosphene field. It is possible to release pressure phosphenes in a part of the peripheral field which is insensitive to light stimuli. Nasally the retina functions to the ora serrata; temporally, although the ora serrata lies 7 mm. behind the limbus the temporal phosphene boundary is 10 mm. behind the limbus, and the limit of light perception 12 mm. The determination of the anterior phosphene boundaries thus confirms the physio-

logical difference between the temporal and nasal parts of the retina. (2 figures.)
Ray K. Daily.

Cibis, P., and Mueller, H. **Studies in local adaptation with Maggiore's projection-perimeter.** Arch. f. Ophth. 148:468-489, 1948.

According to Hering local adaptation is described in the following way. When a person continues to fixate a definite point, a colored stimulus in his peripheral field slowly looses its color and finally disappears completely. The time from the beginning of the stimulation to the disappearance of the colored impression is called the specific time of local adaptation, the time from the beginning up to the disappearance of any impression is called the general time of local adaptation. The authors use Maggiore's projection-perimeter and study the local adaptation of their own visual fields. The results are presented by curves similar to Wertheim's curves for peripheral visual acuity. The authors state that with weak stimuli and for a visual field of 15 degrees, points on different meridians but of the same distance from the retinal point of fixation are functionally equivalent. With stronger stimuli the corresponding points of the various meridians show pronounced differences with respect to functional value.
Ernst Schmerl.

Fabre, P. **Exact determination of axes of astigmatism by alignment of focal lines.** Arch. d'ophth. 8:495-505, 1948.

The author describes a subjective method for the determination of the axes of astigmatism. He notes that the principal meridians in an astigmatic eye are perpendicular to the corresponding focal lines. Certain subjects are ametropic for one of the foci. For example, they see, without accommodating, a star in the form of a straight line. The author's method gives to the subject a method of describing a focal line which he perceives and allows him to indicate exactly the azimuths of the principal meridians of his eye. For the test two types of apparatus are necessary. The first consists of a testing lens of variable power and the second of an apparatus containing a central luminous point around which can revolve a second luminous point. This second luminous point gives a focal line parallel to the first in the field of the test lenses. The subject must be able to move the apparatus in such a way that the two focal lines lie end to end. The alignment of these two images coincides with the direction of the focal lines and the axis of astigmatism. The method by which the apparatus works is described in full detail and is illustrated with drawings. The author claims that this is a precise means of determining the axes of astigmatism and that it also gives information as to the presence or absence of aberration.
Phillips Thygeson.

Granit, R. **The off/on-ratio of the on-off-elements in the mammalian eye.** Brit. J. Ophth. 32:550-554, Sept., 1948.

Some aspects of the micro-electrode work done with the retina of the dark adapted decerebrate cat are reported. The retinal elements are on-elements, off-elements and on-off-elements. The on-elements respond to light with a stream of impulses, the off-elements with a discharge at the cessation of illumination and the on-off-elements combine these two properties. For the discrimination of light and colors the on-off-elements predominate, and were here found to be fully 80 percent of all the elements. There was a tremendous variation in the ratio of the on and off components of the on-off-element (from 1,000 to 0.001) but the purpose of such variation is not known. In general, it is believed that it improves discrimination. It is highly probable that the slow electrical changes induced by light de-

termine the off-on ratio because electrical stimulation strongly affects this relationship. Anatomical organization is probably not fixed and unchangeable; instead the "boutons" at the synapses expand or contract so as to alter the contact surface and thus alter the function.

Morris Kaplan.

Guenther, G. An instrument for the objective determination of the visual acuity. Arch. f. Ophth. 148:430-442, 1948.

Optokinetic nystagmus serves as a basis for the objective determination of the visual acuity. A frame 15 by 15 cm. is placed in front of the examined person at variable distances of one to four meters. Behind the frame a moving strip of paper presents checkerboard designs with squares 2, 5 and 10 mm. in diameter. With varying distances and varying sizes of the designs a variable visual stimulus is offered. When the stimulus passes the threshold and the moving squares can be discriminated as such, optokinetic nystagmus occurs. The normal minimum separabile determined in this way was found to equal two minutes. Ernst Schmerl.

Györffy, A., and Kahán, A. Tolerance of contact lenses. Ophthalmologica 116: 1-6, July, 1948.

The wearing time of contact lenses was significantly lengthened in nine out of fifteen patients by the instillation of a mixture of 0.5-percent antistine and 0.025-percent privine before the insertion of the lenses. The history and theory of the histamine antagonists is reviewed.

Peter C. Kronfeld.

Hartridge, H., and Thomson, L. C. Methods of investigating eye movements. Brit. J. Ophth. 32:581-591, Sept., 1948.

There is controversy concerning the normal existence of rapid oscillations of the eye during fixation. The precision of measurement of the movement must be

within 6 seconds of arc, which corresponds to a cone unit of size. In this article a method is described in which a point of light reflected from the cornea is photographed by means of a camera mounted on a small bench which is held in the mouth of the subject. The movie film used is examined, a single frame at a time, under a microscope. (5 figures.)

Morris Kaplan.

Hecht, S., Hendley, C. D., Ross, S., and Richmond, P. N. The effect of exposure to sunlight on night vision. Am. J. Ophth. 31:1573-1580, Dec., 1948. (3 tables, 4 figures, 10 references.)

Katz, J. Supplementary observations concerning night myopia. Klin. Monatsbl. f. Augenh. 113:170-172, 1948.

In this short article the possible practical implications of the fact that the sensitivity of the human eye varies for various wave length are discussed. There is a difference of 0.4 diopters between the maxima of the sensitivity curves during day vision and those during night vision. This would mean that an emmetropic or fully corrected eye becomes myopic (0.4 diopter) during twilight vision. Experiments in this field are suggested, especially as the correction of optical instruments and of spectacles for night use would be of practical interest. (References.) Max Hirschfelder.

Langer, F. My experience with the Cobalt lamp of Roessler. Klin. Monatsbl. f. Augenh. 110:26-32, Jan.-Feb., 1944.

The use of the Cobalt lamp of Roessler is recommended for subjective refraction. The test is simple, easy for the patient, fast and quite reliable. The patient is seated 175 cm. from the lamp. A blue disc with red margin indicates hyperopia, a red disc with blue margin myopia. Spherical lenses are put in front of the eye until the color arrangement is reversed. Mixed

astigmatism is characterized by a blue line crossed by a red line. The blue line corresponds to the myopic meridian, the red line to the hyperopic. Plus cylinders are given until the astigmatism is corrected and the eye presents a simple myopia. The same cross appears when in myopic or hyperopic astigmatism one meridian is corrected by spherical plus or minus lenses until the interfocal space is reached. By changing the distance between lamp and patient from 175 cm. to 39 cm. the amount of accommodation is tested. Patients with asthenopia exhibit an excess of accommodation. The refraction is completed by having the patient read the Snellen chart. George Brown.

Lebensohn, J. E. **Practical problems pertaining to presbyopia.** Am. J. Ophth. 32:22-30, Jan., 1949. (3 figures, 3 tables.)

Letchworth, T. W. **Stereoscopic vision in monocular aphakia.** Tr. Ophth. Soc. U. Kingdom 66:261-262, 1946.

The author describes his own experience with monocular aphakia. His right eye had 6/12 vision with −1.00 cylinder and the left 6/6 with a +6 sphere combined with +4.00 cylinder at 160°. He was able to get stereoscopic vision through the optical center of the cataract glass only if the head was not moved. The area was gradually increased by sitting before a tangent scale and moving the eyes up, down and laterally. A prism controlled bifocal was not quite so comfortable and he advises the Franklin type. He suggests occluding the periphery of one lens by an opaque material or ground glass and leaving only the central portions free for binocular vision. Beulah Cushman.

Lorenz, R. **Aniseikonia. A simple method for measuring it.** Klin. Monatsbl. f. Augenh. 110:16-25, Jan.-Feb., 1944.

Two pictures, one green and the other red, are displayed on a stereoscope. In aniseikonia the binocular picture is slanted. The percentage of aniseikonia is figured from the angle of slanting.

One hundred fifty-four persons were tested. None of the emmetropic patients had aniseikonia. Therefore, the author questions the existence of a functional aniseikonia. In the myopic group aniseikonia was found only when there was a difference in the refraction. The aniseikonia disappeared when normal binocular vision was obtained with full correction, but persisted when full correction was impossible. In hyperopia aniseikonia was the more frequent and the more marked the greater the difference between the two eyes and the poorer the vision. However, there is no direct proportion between the amount of aniseikonia and the error of refraction. In practice aniseikonia is not too important. It is most frequent and most marked in patients who have poor stereoscopic vision and who, therefore, are not greatly bothered by the aniseikonia. In persons with well developed stereoscopic vision aniseikonia is comparatively infrequent or small. When there is considerable difference between the eyes the patient usually uses one eye only. Such patients, when fully corrected and with good vision of both eyes, complain about dizziness and slanting due to the now apparent aniseikonia. In hyperopia poor vision of one eye or poor stereoscopic vision often prevent the appearance of aniseikonia. There may be complete suppression of one eye in order to avoid aniseikonia. George Brown.

Marchesani, O., and Schober, H. **The action of lactoflavine upon the color vision.** Arch. f. Ophth. 148:420-429, 1948.

After intravenous or intramuscular injections of 10 mg. of lactoflavine the authors found a significant enlargement

of the visual fields for red in 47 persons.

Pacalin, G. **Physiologic diplopia.** Ann. d'ocul. 181:604-612, Oct., 1948.

Diplopia begins with the stimulation of noncorresponding retinal areas. Binocular integration as well as projection, or fusion, are largely accomplished in the peri- and para-striate areas that Brodman has numbered 18 and 19. The subsequent course of binocular visuomotor impulses is not accurately known. Memory impressions, however, largely determine our interpretations of size, form and distance. The well-known steps of Schroeder demonstrate that visual interpretation is not technically correct. Chas. A. Bahn.

Papagno, M. **Acetylcholine effective in a case of spasm of accommodation.** Boll. d'ocul. 27:464-470, July, 1948.

A 17-year-old girl with dysmenorrhea associated with headache, abdominal pain, cardiac palpitations, vomiting, vertigo, and diarrhoea since she was 14, noticed a blurred vision for distance during her two last menstrual periods. Examination revealed normal eyes and retinoscopic refraction of three diopters of miopia. With a −3.00 D. lens, she could read 10/10. Intramuscular acetylcholin injection immediately reduced the spasm from three diopters to one and soon after

to emmetropia. The next menstrual period was accompanied by a slightly milder spasm of accommodation and again relieved by intramuscular acetylcholin.

Siebeck, R. **The form-threshold problem of optical stimuli.** Arch. f. Ophth. 148:443-458, 1948.

If two figures, say a circle and an equilateral triangle of the same area and color, are compared with each other, the triangle appears to be larger than the circle, whereas the color of the circle appears to be more saturated than that of the triangle. Starting from these observations, the author studied the form-threshold problem. He finds a definite relationship between shape and threshold values of the offered stimuli. The field which surrounds stimuli of varying sizes but similar shapes becomes more important the smaller the objects are. This is probably due to the increasing ratio of circumference to area. Unavoidable ocular movements cause differences in local retinal adaptation with different stimuli of the same area but of different shapes. Because of this factor a quantitative correlation between form and threshold cannot be satisfactorily presented. However, it is safe to say the shape of a visual stimulus affects the threshold sensitivity, although the size of the object is of much greater importance. Ernst Schmerl.

Sinclair, A. H. H. **Developmental aphasia.** Brit. J. Ophth. 32:522-531, Sept., 1948.

Developmental aphasia is a failure of visual comprehension probably caused by delayed development of unilateral hemispherical dominance. Letters and words are seen but are not recognised but aural perception remains unaffected and is of great use to the affected children. The condition may be mild and transitory or severe and difficult to overcome. There is a natural tendency to recover which increases progressively with the child's development and education.

The important diagnostic criterion is the brightness of the child in other processes of learning. He can easily read numbers, music or pictures and learns easily by ear but cannot appreciate the printed word. There is most probably an absence or a delay in the myelinization of the neurons going to the exteroceptive centers in the cerebral cortex. Treatment consists of meticulous training by parents and teachers and almost always brings good results.

In the Edinburgh Primary Schools about 10 percent of the children had developmental aphasia, of whom half recovered in the ordinary course of education and half required special treatment.   Morris Kaplan.

Starke, H. **Changes of corneal astigmatism following instillations of eye drops.** Arch. f. Ophth. 148:544-554, 1948.

The author used Hartinger's ophthalmometer as manufactured by Zeiss to measure the radii of corneal curvature in about 40 persons. The instrument permits a determination of the radius with an error of not more than ±0.01 mm. The radii of normal corneas of younger people show changes of several hundredths of a millimeter caused by variation of the ocular tension and the pressure of the eyelids. With instillations of atropine corneal astigmatism usually decreases, with pilocarpine it increases.   Ernst Schmerl.

Tschermak-Seysenegg, A. **One hundred years of "Haidinger brushes."** Klin. Monastbl. f. Augenh. 113:167-169, 1948.

One hundred years ago the mineralogist Haidinger discovered the appearance of a figure like a double-sheaf in polarized light, afterward called "Haidinger's bundles or brushes." The cause for this phenomenon which appears only in light of short wave length is the presence of doubly refracting fiber elements in the macular region of the human retina. The phenomenon serves also as proof for the polarization of the light of the sky which is vertical to the apparent course of the sun. Using doubly refracting prisms before each eye one can use the phenomenon of these brushes for tests of binocular vision. (References.)

Weston, H. C. **The effect of age and illumination upon visual performance with close sights.** Brit. J. Ophth. 32:645-653, Sept., 1948.

Twelve patients of different ages were studied while performing a series of special visual tasks that involved the perception of fairly small detail. Each task was repeated with different degrees of illumination. Each subject had previously been refracted and fitted with necessary glasses and all read fine print with their glasses. They were arranged in five age groups, from 24 to 48 years. The task consisted in finding all the similarly placed gaps in a series of Landolt rings and results were recorded as time per correct ring. Although age had no effect on visual acuity, there was definite and regular effect of age on visual efficiency. The rate of decline is fairly consistent and amounts to about five percent per annum. The effect of illumination changed greatly with age; a change from the lowest to the highest illumination tried increased the performance of the

youngest subjects only 18 percent but it increased the performance of the oldest subjects 400 percent. In addition, it was noted that with the lowest illumination and the finest visual task, the performance of the 24-year-olds was as good as that of subjects of 47 years with the easiest visual task and the highest illumination. Morris Kaplan.

A device embodying a Placido's keratoscopic disk is described. For ordinary keratoscopy Foddis uses a Placido's disk that has two openings in place of the usual central one so that he can study the keratoscopic reflex binocularly. (3 figures.) Harry K. Messenger.

Fried, Carl. Roentgen and radium therapy in ophthalmology. Ophth. ibero am. 9:323-344 (Portuguese), 345-366 (English), 1948.

The results briefly described by the author relate to 28 cases of inflammation of bacterial and 49 of nonbacterial origin, and to 23 of malignant and 5 of benign neoplasms. All patients were treated in the São Francisco de Assis Institute (Brazil). Rather diffuse claims are made for benefit in the inflammatory diseases

and in painful blind glaucomatous eyes. Brief comments are made as to papers published by other authors.

W. H. Crisp.

Gut, A. Indirect illumination in direct ophthalmoscopy. Ophthalmologica 116: 79-85, Aug., 1948.

The conventional method of direct ophthalmoscopy utilizes diffusely reflected light. Indirect illumination is obtained if, by means of an adjustable condenser, the borders of the directly illuminated portion of the retina are sharply focused. The portion of the fundus adjacent to the directly illuminated area can now be examined in indirect light. The method is especially revealing in diseases of the macula. In such cases the light source or its equivalent (the diaphragm of the ophthalmoscope) is brought to a sharp focus below or temporally to the macula while the latter is studied for minute pathologic changes. Six instructive cases are described and depicted. An ophthalmoscope with variable angle between the axes of the illuminating and the observation system is especially suitable for examination in indirect light. The author's main point is that this simple and widely known method is not used as much as it deserves.

Lijó Pavía, J. Papillary edema; comparative study with sodium light. Rev. oto-neuro-oftal. 23:45-51, July-Sept., 1948.

Two cases of papillary edema are presented, one due to malignant arterial hypertension and the other a sequel of hypophyseal tumor. The fundus was studied in ordinary white light, red-free light, and sodium light. With yellow light,

in the case of malignant neuroretinitis, the vessels were well demarcated, superficial precapillaries and peripapillary lipoidal deposits were visible and the macula was more precise, though the fovea could not be delimited. In the second case, too, sodium light ophthalmoscopy resulted in finer visualization of the vascular system and the exudative deposits. (5 figures.)

Edward Saskin.

Morgan, O. G. The value of vitamins in ophthalmology. Medical Press 220:385-389, Nov. 10, 1948.

Many serious diseases of the eyes are associated with poor general health. It is usually worth while to supplement local treatment with vitamins B and C. The outstanding effect of vitamin A deficiency is xerosis and night blindness. Retrobulbar neuritis and increased corneal vascularization may be due to thiamine deficiency. Rosacea keratitis responds to riboflavin therapy. Ascorbic acid has been used in corneal ulcer and keratitis of various types with satisfactory results. Vitamin D regulates calcium and phosphorus metabolism. Vitamin D has been suggested in myopia in the child. Rutin or vitamin D decreases capillary fragility. It neutralizes the effect of potassium thiocyanate in hypertension. I. E. Gaynon.

Pérez Toril, Francisco. Penicillin in ocular diseases. Arch. Soc. oftal. hispanoam. 8:833-838, Aug., 1948.

From his experience with the use of penicillin in 87 cases of ocular disease, Pérez concludes that penicillin is of great value in ophthalmology. Its employment is not necessary in diseases easily amenable to other forms of therapy but should be used promptly when irreparable damage seems immanent. Intramuscular and intravenous administration is adequate for extraocular lesions but intraocular lesions require subconjunctival, intra-

vitreal, and intracameral administration in addition to the use of collyria, ointments and baths. Agents for local application should contain not less than 500 units and not more than 10,000 units per cc. of solution. The early use of penicillin has modified the grave prognosis formerly associated with such diseases as gonorrheal ophthalmia and serpigenous ulcer.

Vannas, Mauno. The diagnosis of intraocular tumors and foreign bodies by means of anterior pupillary transillumination. Acta ophth. 26:125-134, 1948.

The limitations of posterior bloodless diascleral transillumination and of posterior transillumination with the transilluminator introduced far back through a conjunctival incision are discussed. The main source of error is the uncertainty of the position of the transilluminator in relation to the tumor. In addition, in diascleral transillumination the pupil becomes illuminated only if the eye of the examiner is within the light cone whose point is formed by the point of the lamp and whose aperture is the pupil. If the examiner moves his head, or the patient his eye the iris comes between the lamp and the eye of the examiner, and the pupillary reflex is complicated by two shadows, that of the tumor, and that of the iris. Transillumination through the pupil with the transilluminator applied directly to the cornea is superior. Also, with this method, experiments in transillumination on enucleated eyeballs demonstrated that shifting the point of light

from the center of the cornea over the iris greatly reduces the transillumination of the sclera. Pupillary transillumination is of value also for localizing purposes in cases of foreign bodies in the wall of the eyeball or its vicinity. Foreign bodies in the wall of the eyeball or in contact with the inner surface of the retina are recognized by distinct shadows; when the experimental object is transferred inward into the virtreous its shadow becomes less distinct. Clinical case reports illustrate the superiority of pupillary over diascleral transillumination.   Ray K. Daily.

Velhagen, K. **Technical arrangement for the dark adaptation test.** Klin. Monatsbl. f. Augenh. 113:170, 1948.

The author recommends a lightproof cabinet which can be arranged in the corner of any room. The patient sits within the cabinet and observes the adaptometer, which is built within the side of the cabinet and can be regulated from the outside. Such an arrangement leaves the examiner free for other duties during the time-consuming test.

           Max Hirschfelder.

6

OCULAR MOTILITY

Abraham, S. V. **A new classification of nonparalytic strabismus** Am. J. Ophth. 32:93-98, Jan., 1949. (1 table, 19 references.)

Anderson, J. R. **Sidelights on the inferior oblique muscle.** Brit. J. Ophth. 32: 653-667, Sept., 1948.   -

This detailed discussion of the inferior oblique muscle emphasizes the need of a knowledge of its anatomy and physiology in adequate diagnosis and selection of treatment of its disorders. Its insertion into the sclera is oblique and about 10 mm. in length which lies in and below the horizontal meridian. It is under the external rectus, its anterior end being 2 mm. above the lower level and almost 10 mm. behind the insertion of the external rectus. Its insertion extends to a point 4 mm. from the fovea. Its function is considered to be 56.1-percent extorsion and 42.9-percent elevation. The very early anatomists called the inferior obliques the amatorii or lovers' muscles since rolling of the eyes were signs of affection.

Often in diagnosis the malfunction of a muscle is ascribed to overaction, underaction or palsy of the inferior oblique when actually the contralateral or homolateral antagonist or yoke muscle is defective. The surgeon must be very careful to correct large horizontal errors before he deals with most vertical defects, as the latter may then become only negligible sources of disfunction. (38 references.)   Morris Kaplan.

Angius, Tullio. **The treatment of the heterophorias.** Rassegna ital. d'ottal. 17: 190-196, May-June, 1948.

While employing acetylcholine in the treatment of chorioretinitis and accommodative spasm, the writer noted a regression of the concomitant heterophorias. The subjects reported upon in the article were in good health and were emmetropic. The muscle balance was studied by various methods, among them with Maddox rod, stereoscope and prisms. The subjects were divided into five groups according to the medication administered. The first group received daily intramuscular injections of acetylcholine bromide, the second prostigmin intramuscularly, the third intravenous vitamin B_1, the fourth d-phenylisopropylmetilamine chloride, and the fifth group vitamin A, 100,000 units and D 25,000 units by mouth.

It was observed that fatigue, even though not excessive, caused an aggravation of the heterophoria, especially in older subjects. Heterophoria was often associated with spastic conditions else-

where, in the colon, for example. Excellent results were obtained in the patients receiving prostigmin and those getting vitamin B_1, either alone or combined. Esophorias showed a greater tendency to recur than other phorias. The treatment was more effective than orthoptic measures, but in the more severe cases a combination of the two yielded better results.

Eugene M. Blake.

Apin, K. Exercises in strabismus. Klin. Monatsbl. f. Augenh. 110:62-67, Jan.-Feb., 1944.

The first important step is the measurement of refraction after instillation of atropine for three successive days. Full correction with the eyes still under the action of atropine is indicated and permanent occlusion, if amblyopia of one eye is found. Next the strabismus should be eliminated, if necessary by surgery. Exercises are kept up for years in order to reestablish binocular and stereoscopic vision.

George Brown.

Da Pozzo, Ezio. A case of post-traumatic synkinesia oculo-oculare. Giorn. ital. di oftal. 1:265-273, May-June, 1948.

In a girl cranial trauma initiated a synkinesia oculo-oculare (blepharoptosis of one side associated with contraction of the contralateral medial rectus). The author discusses briefly the hypotheses advanced in explanation of congenital and acquired synkinesis with involvement of the levator palpebrae. He concludes that none solves the problem of the pathogenesis of this picture.

Francis P. Guida.

Gasteiger, H. Rare complications after surgery for strabismus. Klin. Monatsbl. f. Augenh. 113:152-157, 1948.

Postoperative complications after surgery for strabismus are rare. Three cases in which severe inflammation and necrosis of the sclera developed in the operative area after tenotomy or advancement are described. In one a deep keratitis also developed but it finally healed with severe loss of vision due to the scar. One of the three eyes had to be enucleated, whereas the other two could be saved through removal of the necrotic conjunctival and scleral tissue and covering of the defect by a flap of conjunctiva and Tenon's capsule. The author believes that these complications are nutritional and due to disturbances of the blood supply. He points out that the anterior ciliary arteries enter the bulbus in this region and that they suffer damage during surgery. The other possibility is infection of the operative field. Lowered resistance in the patients may have contributed to the abnormal course. (References.)

Max Hirschfelder.

Hartmann, E. Physiology of ocular motility, heterophoria and strabismus. Ann. d'ocul. 181:449-462. Aug., 1948.

Ocular motility, normal and abnormal, involves coördinated, binocular, three-dimensional alignment as well as motion. As practically all ocular motility is subconscious, its quantity and quality are governed by numerous reflexes in which the eyes play a more or less dominant part. For example, postural reflexes include both static and dynamic types. The former involves the "righting" and altitudinal reflexes which are primarily located below the cerebral peduncles. Static-kinetic reflexes involve binocular alignment associated with head rotation. They are involved in nystagmus following especially rapid head rotation and are primarily located in the semicircular canals and vestibular nuclei. Retinal reflexes form part of the sensorial reflex mechanism which also includes smell, hearing, touch and taste and which is an important factor in reflex ocular motility. The visual reflexes involved in binocular alignment and motility include the fol-

lowing: "righting," direction, compensating, fixation, retinal orientation and convergence reflexes. The convergence reflex, the most recently acquired, is most frequently involved in strabismus. It is essentially a conditioned reflex and the others are true or unconditioned. The 45-degree deviation of the axes of the orbits from parallelism results in differences of alignment which are compensated in the phorias but not in the tropias. Muscular anomalies alone, as in the Duane syndrome, seldom play a dominant part in strabismus. It usually is a manifestation of imperfectly coördinated reflexes which produce disalignments. All treatment, surgical and other, should be designed primarily to coördinate faulty reflexes rather than increase or decrease the power of a muscle. (13 references.)

Chas. A. Bahn.

Law, F. W. A point for consideration in the use of the stereoscope. Brit. J. Ophth. 32:639-644, Sept., 1948.

Heretofore the answer to the question "what happens to the inclination of the visual axes on moving the stereogram in a stereoscope towards or away from the observer?" has simply been guessed at. From studies involving the interocular distance, the distance of the card from the viewer, the width of the stereogram and the strength of the lenses in the stereoscope, the author found that the instrument could be used for exercise either of convergence or divergence but to be successful the examiner must understand the principles exactly. With this in view, tables are presented to keep the necessary data perspicuous.

Morris Kaplan.

Riise, Per. Surgical treatment of vertical squint. Acta ophth. 26:153-165, 1948.

The field of surgery of the vertical and oblique muscles has widened. Elschnig's book on surgery in 1922 speaks of these

operations as rare. In Thiel's recent book the surgical indication is a squint of more than 5 degrees. The results of surgery for vertical strabismus are shown by case reports illustrated with photographs and diplopia charts. (31 figures.)

Ray K. Daily.

Spaeth, E. B. The vertical element in the causation of so-called horizontal concomitant strabismus. Surgical principles for the vertical corrections. Am. J. Ophth. 31:1553-1566, Dec., 1948. (21 figures.)

Toth, Zoltan. Forceps in resection of a muscle. Klin. Monatsbl. f. Augenh. 110: 67-68, Jan.-Feb., 1944.

The use of a forceps in advancement or resection of a muscle has many disadvantages. The instrument is too big for the small field and the trauma to the muscle is considerable. A simple bridle suture through the muscle before the insertion is cut serves the same purpose and is technically preferable.

George Brown.

Weekers, L., and Weekers, R. A monocular operation for severe divergent strabismus. Ann. d'ocul. 181:493-499, Aug., 1948.

A provisional attachment is made of the internal rectus tendon across the cornea to the external rectus tendon. In very high degrees of strabismus tenotomy of the external rectus is also performed. In strongly amblyopic divergent eyes, this operation is recommended from a cosmetic point of view as simple and safe. Anesthesia includes local instillation and retrobulbar injection, without conjunctival infiltration. The external rectus muscle is raised with a forceps and a double thread is passed between the sclera and the muscle immediately behind the tendon, forming a strong support for traction. The conjunctiva over the internal rectus is then dissected, sutured,

and sectioned. The conjunctiva and tendon are placed across the cornea and are sutured to the tendon of the external rectus. Both sutures are now united. The conjunctiva and advanced internal rectus tendon cover the cornea. After seven days the sutures and the tongue of conjunctiva are removed.

The advantages of this procedure are its simplicity and safety in all types of divergent strabismus of 25 to 35 degrees or more. (9 references.) Chas. A. Bahn.

Wilhelm, G. **Treatment of amblyopia.** Klin. Monatsbl. f. Augenh. 110:56-62, Jan.-Feb., 1944.

In 11 children, 2 to 10 years old, with strabismus and amblyopia of one eye, improvement followed permanent occlusion in 90 percent in two to four weeks. Normal vision was achieved in 11 percent of those whose initial vision was 5/10, in 70 percent with vision of 5/25 and in 34 percent with less than 5/50. The necessary time of occlusion was independent of the age, but longer with lower initial vision. Treatment of amblyopia should be started before the sixth year, but is possible after this age. In 42 percent the amblyopia recurred, especially in children of two to four years. After repeated occlusion, lasting results were eventually attained in 85 percent of patients. Subsequent amblyopia of the occluded eye occurred in 46 percent of the two to four year old children, never after the sixth year. In 46 percent the strabismus disappeared after elimination of the amblyopia and prescription of glasses.

CONJUNCTIVA, CORNEA, SCLERA

Alvarez Alvarez, Abundio. **The therapy of herpetic ocular diseases.** Arch. Soc. oftal. hispano-am. 8:687-698. July, 1948.

The literature on the numerous thera-

peutic agents used in these conditions is reviewed, and three cases of herpetic keratitis treated with applications of an alcoholic solution of iodine and potassium iodide are reported. One case of herpes zoster ophthalmicus responded to the administration of chromesulfur.

Ray K. Daily.

Anderson, Banks. **Corneal and conjunctival pigmentation among workers engaged in manufacture of hydroquinone.** Arch. of Ophth. 38:812-826, Dec., 1947.

Observations are presented on a group of workers employed in the manufacture of quinone and hydroquinone in whom certain characteristic lesions of the cornea and conjunctiva have developed. These lesions consist of a variable degree of pigmentation of the interpalpebral portions of the conjunctiva and cornea, proportional to length of employment and to age and corneal changes. These corneal changes consist in pitting and erosion of the corneal surface, thinning of the cornea, development of irregular pigmented or staining areas, wrinkling or modification of Descemet's membrane and, possibly, keratoconus. The changes are apparently reversible up to a certain point in that conjunctival staining may disappear. The corneal stain is more permanent. The lesion could not be produced in albino rabbits. While the chemical is said not to belong to the carcinogenic group, some of the lesions resemble Bowen's disease. The development of a frank malignant growth is not beyond the bounds of probability. John C. Long.

Bakker, A. **A myxo-haemangioma simplex of the conjunctiva bulbi.** Brit. J. Ophth. 32:485-88, Aug., 1948.

A pedunculated hemangioma of the conjunctiva under microscopic examination showed intensive growth with mitotic figures and myxomatous degenera-

tion. There has been no recurrence eight months after simple excision.

Orwyn H. Ellis.

Blodi, F. A case of a horizontal Krukenberg splindle. Acta. ophth. 26:373-378, 1948.

A case of bilateral horizontal Krukenberg spindle is reported in a woman 76 years old. The spindle was demarcated by a glassy line situated in the posterior corneal layers and visible only in indirect light. There was no other abnormality in the eyes. The etiology is believed to be a change in Descemet's membrane, limited by the glassy line. Although the change could not be demonstrated biomicroscopically it is believed that colloidochemical changes in the endothelial cells could account for the deposit of pigment on the posterior corneal surface.

Ray K. Daily.

Bonavolontà, Aldo. Biomicroscopic examination of the limbus as a basis for a new classification of the various stages of trachoma. Giorn. ital. di oftal. 1:207-226, May-June, 1948.

The author studied the corneal manifestations said to be pathognomonic of trachoma. These manifestations may be grouped into quite variable complex pictures. Several groups are of very little interest, namely the sign of the crescent, the kaleidoscopic sign, and the disappearance of the primary sulcus; others are of definite value, namely the accelerated development of the terminal limbal loops, and the superficial neovascularization with the characteristic accompanying infiltration. Of greatest value are the nodules and their residua. He points out the value of biomicroscopic examination of the limbus to reveal and evaluate these manifestations and to establish the diagnosis of trachoma from its incipiency to its end. He noted several cases in stage 1 and 2 with corneal signs and others without. It seems important to him to establish a classification based on the biomicroscopic findings which takes into consideration the conjunctival and corneal picture. He suggests one in which T_a includes T_1 and T_2 of MacCallan, without corneal signs of trachoma, T_b consists of those cases in T_1 and T_2 which show corneal signs, and T_c consists of cases in T_3 and those in T_4 in which examination of the cornea shows active trachoma. The fully evolved trachoma, both corneal and conjunctival is known as T_d.

Francis P. Guida.

Brand, E. A new quick staining procedure of the inclusion bodies of trachoma. Orvosi Hetilap 26:405-406, 1948.

Report on a new, simple and quick procedure lending itself to demonstration of the inclusion bodies of trachoma. A 1-percent solution of toluidine blue stains the inclusion bodies with due contrast in one-half minute.

Gyula Lugossy.

Brand, E. A new quick staining method for trachoma inclusions. Ophthalmologica 116:61-63, July, 1948.

The material is spread on a clean slide, allowed to dry at room temperature, fixed in absolute alcohol for ½ minute, dried again and stained with a 1-percent aqueous solution of toluidine blue for two minutes. The author believes that the trachoma inclusions are actually a part of the Golgi network altered by the trachoma virus.

Peter C. Kronfeld.

Busacca, A. Certain corneal diseases observed under the influence of penicillin therapy. Ophthalmologica 116:43-50, July, 1948.

The author describes his experiences with penicillin applied topically in diseases of the lids, conjunctiva and cornea.

He reports good results with penicillin injections (5,000 units per cc.) into the lid in cases of severe chronic blepharitis. He uses the same technique for hordeola. The course of a large portion of infectious ulcers of the cornea is rapidly and beneficially changed by repeated subconjunctival injections of penicillin. Specifically, he describes two types of keratitis which have responded surprisingly well to subconjunctival penicillin therapy. He proposes the term "keratitis epithelialis desquamativa" for the first type which is characterized by epithelial infiltration and ulceration in the form of small dots arranged in lines or coalescing into larger spots with irregular (geographic) borders. The disease takes a chronic course and may be resistant to all conventional forms of therapy. Busacca has cured two such cases with daily subconjunctival injections of penicillin continued for approximately four weeks. For the other type of keratitis which belongs to the phlyctenular group, Busacca proposes the term "keratitis with polymorphous efflorescenses." The first type has been thought to be of herpetic and the second type of allergic origin. In the light of their favorable response to penicillin Busacca believes that the views concerning their pathogenesis will have to be revised.

Peter C. Kronfeld.

Colditz, Heinz. Keratoconus, operated on according to Sato. Klin. Monatsbl. f. Augenh. 110:233-234, March-April, 1944.

In an eye with rapidly progressing keratoconus in a 25-year-old woman, a discission-knife was introduced and three vertical incisions were made in Descemet's membrane in the area of the conus. The swelling and opacity of the involved area subsided very slowly. Nine months later the curvature of the cornea was almost normal. There was a dense scar at the site of the former apex. The cornea here was much thicker than before the operation. George Brown.

Coverdale, H. Some unusual cases of Sjögren's syndrome. Brit. J. Ophth. 32: 669-673, Sept., 1948.

Sjögren's syndrome (keratitis sicca) is part of a general systemic disturbance of unknown origin. There seems to be no common causative factor. Probably a majority of cases occur in women near the menopause. The case histories of five patients are presented whose eyes had the typical manifestations but whose histories were somewhat unusual. Two occurred in a man and his daughter who had had dry eyes all their lives. The daughter showed signs of pituitary dysfunction. Two others occurred in a woman and her tuberculous daughter, and the fifth in a young woman whose symptoms seemed to originate from a fracture at the base of the skull. Morris Kaplan.

Edström, G., and Österlind, G. A case of nodular rheumatic episcleritis. Acta ophth. 26:1-6, 1948.

In the course of a chronic destructive polyarthritis a patient developed a bilateral nodular episcleritis with a secondary rise in tension. Two nodules were excised from the left eye; one was subjected to histologic examination, and the other was used in a guinea pig test and culture on Loewenstein's medium. The tests for tuberculosis were negative. The nodules were covered with a normal conjunctival epithelium and consisted of granulomatous tissue; collagenous fibrils radiated from the periphery toward the center, which was necrotic. There were collections of large bright, fibroblastoid cells in the periphery and the adjacent fibrous tissue was infiltrated with plasma cells. The disease was fatal and at autopsy in addition to the lesions in the joints

rheumatic granulomas were also found in the myocardium. (2 figures.)

Ray K. Daily.

English, P. B., and White, J. Mc. B. Corneal transplantations. M. J. Australia 1:736-738, June 12, 1948.

The most popular operation is described as a circumscribed penetrating keratoplasty 4 to 6 mm. in diameter. A brief review of the methods used by Castroviejo, Thomas, Filatov, and Weiner and Alvis is given. Corneal transplantation is most likely to succeed when there is no increase in ocular tension, and when the only lesion in the eye is a partial leucoma of the cornea. Aphakia, extensive corneal opacity, increased ocular tension, and corneal vascularization are all unfavorable factors.

An iridectomy should be done if there are synechia which may complicate the surgery. The donor eye should be a young one and if removed from a cadaver should be obtained within 24 hours after death. Eyes doomed to failure become cloudy and vascularized early. Negroid and caucasian corneas may be interchanged. The only case operated in a member of the Australian fighting forces is described. A visual acuity of 6/36 was obtained two months after surgery.

Fadda, A., and Zambetti, E. The prophylaxis of ophthalmoblennorrhea by use of penicillin ointment. Rassegna ital. -d'ottal. 17:207-217, May-June, 1948.

The authors at first used an ointment containing 500 units of penicillin per gram of a vaseline base and kept refrigerated. Later a thermolabile ointment was produced which was not subject to hydrolytic influence. These ointments were employed in a large series of newborn infants for a period of a year. The ointment was inserted into the conjunctival sac immediately after birth and its use continued twice a day for five days. In only two instances was there any acute conjunctivitis and these responded to a two-hour use of the ointment. In no case was any irritation noted in the conjunctiva, cornea or lids. The year's experience with the special anhydrous penicillin ointment demonstrated that it was a good substitute for silver nitrate in the prophylaxis of ophthalmia of the new-born.

Eugene M. Blake.

Jirman, J. Treatment of rosacea keratitis. Ann. d'ocul. 181:475-484, Aug., 1948.

The process may be marginal or central or both, and nodular or tongue shaped. There is usually corneal infiltration and progressive or recurrent ulceration, and necrosis and vascularization are variable. The differential diagnosis includes other degenerative, low grade or inflammatory diseases such as scrofula, tuberculous lesions and Mooren's ulcer. Several factors take part in the cause, such as a constitutional predisposition, vasomotor degeneration, exposure to physical or chemical irritants, skin parasites such as the demodex folliculorum and such body catalysts as sex hormones and vitamins, especially riboflavin.

A case of rosacea keratitis in both eyes of a 50-year-old woman is discussed in detail. A conjunctival flap over the diseased area arrested its progress, especially in one eye.   Chas. A. Bahn.

NEWS ITEMS

DEATHS

Dr. Warren Douglas Horner, San Francisco, died October 22, 1948, aged 58 years.

Dr. David L. Tilderquist, Duluth, Minnesota, died September 26, 1948, aged 76 years.

Dr. Edward Andrew Weisser, Pittsburgh, died October 18, 1948, aged 72 years.

ANNOUNCEMENTS

OREGON POSTGRADUATE CONVENTION

The 10th annual spring postgraduate convention in ophthalmology and otolaryngology will be held in Portland, Oregon, June 19 to 24, 1949. Guest speakers who will appear on the fine program, arranged by the Oregon Academy and the University of Oregon Medical School, will be: Dr. Lawrence R. Boies, professor of otolaryngology, University of Minnesota Medical School; Dr. Leland Hunnicutt, associate clinical professor of otolaryngology, University of Southern California; Dr. James H. Allen, professor of ophthalmology, Iowa State University School of Medicine; and Dr. Edmund B. Spaeth, professor of ophthalmology, Graduate School of Medicine, University of Pennsylvania.

In order to make the course more personal and practical, registration will be limited to 125. For preliminary programs and full information, write to: Dr. David D. DeWeese, 1216 West Yamhill Street, Portland 5, Oregon.

KERATOPLASTY SYMPOSIUM

A two-day symposium on keratoplasty will be held in the lecture room of the Manhattan Eye, Ear, and Throat Hospital, 210 East 64th Street, New York City, on April 19th and 20th.

This conference will consist of operative clinics on the morning of April 19th, follow-up clinics on the morning of April 20th, papers by men from the United States and abroad on the afternoon of April 19th, and on the afternoon of April 20th, a round-table discussion.

ORTHOPTIC EXAMINATION

Application for the examinations to be conducted by the American Orthoptic Council during September and October, 1949, will be received by the office of the secretary, Dr. Frank D. Costenbader, 1605 22nd Street, N.W., Washington 8, D.C., and must be accompanied by the examination fee of 25 dollars. Applications will not be accepted after July 1, 1949.

N.S.P.B. MEETING

The National Society for the Prevention of Blindness will hold a 3-day national conference at the Hotel New Yorker, New York City, on March 16th, 17th, and 18th. The theme of the meeting will be "The battle against blindness: The next 40 years," and the following subjects will be discussed: "Eye problems in middle life," "The eyes of children and young adults," "Vision in industry," "Medical advances in sight conservation," and "Glaucoma: A community problem."

MISCELLANEOUS

ORTHOPTIC SCHOOL

A school of orthoptics has been started at the Massachusetts Eye and Ear Infirmary in conjunction with Simmons College in Boston. Students at the college, during the first three years, take courses that will give them an adequate scientific background. Their fourth year is spent at the hospital where practical and didactic work in orthoptics and perimetry is given. This 4-year program leads to the degree of Bachelor of Science and the Diploma in Orthoptics. Miss Ann Stromberg is technical director of the practical aspects of the work at the hospital.

BETTER VISION INSTITUTE

A record attendance of 81 members and guests marked the January 21st meeting of the Better Vision Institute in New York City. Mr. M. J. Julian, president, spoke of the new program which is being designed to combat the misinformation that has been spread regarding the practices of the ophthalmic industry, particularly along economic lines.

SOCIETIES

CLEVELAND MEETINGS

The guest speaker for the January dinner meeting of the Cleveland Ophthalmological Club was Dr. Richard G. Scobee, director of graduate study in ophthalmology, Washington University, Saint Louis, who spoke on "Versions: The case against prisms." Dr. Scobee's presentation was most instructive and interesting and was illustrated by excellent lantern slides.

Dr. James S. Shipman, clinical professor, Graduate School of Ophthalmology, University of Pennsylvania, and attending surgeon at Wills Hospital, was the speaker at the first dinner meeting of the club in November. Dr. Shipman spoke on "Some practical points regarding retinal detachment surgery." His talk was most practical and he brought out several new points in the treatment of detachment of the retina. A lively discussion followed his presentation.

BROOKLYN PROGRAM

Papers presented at the 107th regular meeting of the Brooklyn Ophthalmological Society on February 17th were: "Psychology of cataract sur-

gery considered from the standpoints of surgeon and patient," Dr. Daniel B. Kirby, New York; and "Some unusual optic nerve conditions which may be confused with papilledema," Dr. Frank B. Walsh, Baltimore. During the instruction session, Dr. Charles A. Perera, New York, spoke on "The pathology and treatment of retinal detachment."

SOUTHERN RESEARCH SECTION

On October 26, 1948, during the meeting of the Southern Medical Association in Miami, Florida, the southern section of the Association for Research in Ophthalmology was organized. Dr. Conrad Berens gave a brief resume of the development and achievements of the national association. Dr. George Haik presented further work on "Beta irradiation for glaucoma." Dr. Alston Callahan, Birmingham, Alabama, was asked to serve as chairman of the southern section for the coming year.

The following ophthalmologists attended: Dr. Conrad Berens, Dr. Shaler Richardson, Dr. George Haik, Dr. William Sayad, Dr. Don Boles, Dr. Johnson, Dr. William Hester, Dr. Karl Benkwith, Dr. Sam McPherson, Dr. Carl Dunaway, Dr. Stacy Howell, Dr. Curtis Benton, Jr., Dr. Hugh Parsons, Dr. E. R. Veirs, Dr. Frank Costenbader, Dr. Mason Baird, Dr. Philip M. Lewis, and Dr. Alston Callahan.

READING MEETINGS

The 88th and 89th regular meetings of the Reading Eye, Ear, Nose, and Throat Society were held on January 5th and 19th. Dr. N. A. Karakashian, of Philadelphia, spoke on "Practical perimetry," at the first meeting; Dr. E. Gerard Smith of Lancaster, Pennsylvania, discussed "The principles of gonioscopy," at the second meeting.

MILWAUKEE SPEAKER

Dr. I. E. Gaynon was the ophthalmic speaker at the January 25th meeting of the Milwaukee Oto-Ophthalmic Society. His subject was "Herpes zoster disciform keratitis."

FLORIDA ANNUAL MEETING

The 10th annual meeting of the Florida Society of Ophthalmology and Otolaryngology will take place at the Belleview-Biltmore Hotel, Belleair, Florida, on April 10th. The address of welcome will be delivered by the president, Dr. Bascom H. Palmer, Miami. A paper, "Benign tumors of the esophagus," will be given by Dr. Thomas M. Edwards, Tampa, and discussed by Dr. Joseph W. Taylor and Dr. C. Frank Chunn, Tampa.

Dr. Charles W. Boyd, Jacksonville, will present a paper on "Corneal section and suture in cataract operation," which will be discussed by Dr. Walton B. Wall, Jr., Orlando, and Dr. Sherman B. Forbes, Tampa. The annual report of the Florida Council for the Blind will be made by the executive secretary, M. Robert Barnett, of Tampa.

At the evening session, Dr. Algernon B. Reese of New York will present a paper on "The treatment of tumors of the eye and adnexa," and Dr. Louis H. Clerf of Philadelphia will speak on "Paralysis of the larynx."

ORTHOPTIC TECHNICIANS MEET

The western group of the American Association of Orthoptic Technicians met at the University of California Hospital, San Francisco, on February 18th and 19th.

PENNSYLVANIA PROGRAM

The annual meeting of the Pennsylvania Academy of Ophthalmology and Otolaryngology will be held April 22nd, 23rd and 24th, at the Penn Harris Hotel, Harrisburg.

Among the speakers who will present papers at this meeting will be Dr. A. D. Ruedemann, Dr. J. R. Lindsay, Dr. R. O. Rychener, Dr. C. S. Nash, Dr. J. G. Linn, Dr. Arno Town, and Dr. G. M. Coates.

In addition to formal presentations, the meeting will include a round table discussion on "Headaches" which will include representatives of all major specialties, and there will be a study club to discuss "Cataract problems," the discussers to include Dr. Ruedemann, Dr. Rychener, and Dr. Town.

The officers are: President, Dr. James J. Monahan; president elect, Dr. Daniel S. Destio; secretary, Dr. Benjamin F. Souders.

EGYPTIAN MEETING

The annual meeting of the Ophthalmological Society of Egypt was held at the Memorial Ophthalmic Library, Giza, Egypt, on March 4th and 5th.

PERSONALS

Dr. Everett L. Goar, Houston, Texas, presented the fifth annual Sanford R. Gifford Memorial Lecture before the Chicago Ophthalmological Society on January 17. The subject of Dr. Goar's paper was "Corneal dystrophies."

Dr. F. Herbert Haessler, Milwaukee, abstract editor of the JOURNAL, has been appointed professor of ophthalmology at the Marquette University School of Medicine.

Dr. Saul Kottler, Cleveland, announces the opening of his office in the Guardian Building. Dr. Kottler recently completed his internship in the ophthalmological division of the University Hospitals, Cleveland.

PRESCRIPTION OPTICIANS

POSTGRADUATE CONFERENCE IN NEUROMUSCULAR ANOMALIES OF THE EYES

The Children's Memorial Hospital, Chicago

By George P. Guibor

For Graduates in Medicine   May 1-6 inclusive

Course Includes Theoretical and Practical Surgical and Non-Surgical Examinations and Treatments

1. Anatomy
2. Physiology
3. Discussion of Patients with Squint
4. Examination of Patients by Students

No Registrations Accepted After April 20   Fee $50.00

For Further Details Apply to the Secretary of Course

The Company was formed in 1916 with the object of establishing a representative Journal of Ophthalmology for the British Empire. For this purpose the Company has incorporated the three existing Ophthalmic publications known as

The Royal London Ophthalmic Hospital Reports, The Ophthalmic Review, and *The Ophthalmoscope.*

measured 27 mm. and the left eye measured 19 mm. (fig. 1). The proptosis of the right eye was apparent grossly. There was no bruit and no pulsation of the right globe. The right globe could be pressed back into the orbit with no more than normal resistance. Pupillary responses to light and convergence-accommodation were prompt and equal in both eyes. There were no palsies of the extraocular muscles. The left fundus appeared normal and the right fundus showed temporal pallor of the nervehead.

Visual field studies of the right eye, with 3/330 white, 1/330 white, and 1/2,000 white, showed peripheral contraction, more marked temporally, with hemianopic characteristics. The left field was within normal limits to all visual angles.

It was the impression of Dr. Chamlin that the visual fields suggested interference with the right optic nerve retrobulbarly extending rather far back toward the chiasmal area (figs. 2 and 3).
Fig. 1 (Grino and Billet). *Case 1.* Showing proptosis of the right eye.

Laboratory data. Urine was within normal limits. Blood hemoglobin was 13.5 gm.; R.B.C., 4.62 million; W.B.C., 6,600, with essentially normal differential; B.U.N., 14.9 mg. percent; blood sugar, 90 mg. percent; serum albumin, 4.4 mg. percent; serum globulin, 2.6 mg. percent; B.M.R. was —11.

Electrocardiography revealed a normal sinus rhythm. Electro-encephalography revealed a minor degree of change from the

Fig. 2 (Grino and Billet). *Case 1.* Visual fields on November 6, 1947, for 1/330 white. Visual acuity in the right eye was 15/100+1; in the left eye, 15/15.

...or was found
...done, including
...patient felt better but

The Royal London Ophthalmic Ho...

Ophthalmoscope.

X-ray examination of the orbits after air insufflation in the postero-anterior view did not disclose any air pockets. In the lateral position there was a very thin layer of air retrobulbarly in the superior portion of the orbital cavity. No tumor was outlined.

On November 12, 1947, a right common carotid arteriogram under general anesthesia was done percutaneously by one of us.

The venograms show a somewhat rounded density, measuring approximately 25 cm. in diameter, within the region of the right orbit posteriorly. A less well-defined density with rather indefinite borders is visible intracranially just above the lesser wing of the sphenoid on the right. These densities were not visible on the preliminary skull films and probably represent capillary circulation in neoplastic masses.

The arteriogram also reveals the just described masses in the region of the right orbit and behind the right lesser wing of the sphenoid. The retro-orbital density is rather poorly defined.

Conclusion. The changes described indicate the existence of a tumor mass in the right orbit, extending possibly retro-orbitally. The intraorbital portion of the mass appears to be highly vascularized (fig. 6). The patient was discharged from the hospital on November 17, 1947, with the diagnosis of retrobulbar tumor of the right eye, probably a hemangioma.

She received roentgen therapy—a total of 16,600r. over a period of one month, from November 28, 1947 to December 29, 1947— through right anterior and lateral portals to the right orbit. Repeated checks of visual acuity, visual fields, and Hertel exophthalmometer readings showed (February 10, 1948) no change in her ocular status.

Ocular examination on June 22, 1948, six months after X-ray treatment, revealed a marked improvement in visual acuity: O.D., from 15/100 to 15/40. There was no ...ession of the exophthalmos, and no ... in the fundus picture in this eye. ...'1 study with 20/2,000 red re-

Fig. 6 (Grino and Billet). *Case 1.* Right carotid angiography. Venogram showing tumor pointed by arrows. Arrow 2 shows the intracranial extension.

vealed macular sparing to account for the improved acuity (fig. 7).

CASE 2

History. O. H., a 55-year-old white man, had had a left nephrectomy about 8 years ago for painless gross hematuria. Four years ago, the patient developed blurring of vision and proptosis of the left eye. At that time, Dr. Davidoff performed a left exploratory frontal craniotomy. No tumor was found and a decompression was done, including orbital decompression.

For some time, the patient felt better but blurring and proptosis recurred. About one year ago at the Medical Center, a biopsy

Fig. 7 (Grino and Billet). *Case 1.* Visual fields on June 22, 1948, after roentgen therapy: R.E., 20/2,000 red; L.E., 1/2,000 white. Visual acuity: R.E., 15/40; L.E., 15/15.
Fig. 8 (Grino and Billet). *Case 2*. Demonstrating proptosis and ophthalmoplegia of the left eye.

from a tumor behind the left eye (via inferior orbital route) was done and was reported to be a hemangioma.

Four months prior to admission to Montefiore Hospital, the patient developed weakness in the left arm and attacks of tachycardia. Three months before admission, his left leg became weak. For the last month prior to admission, it was necessary for the patient to rush to the bathroom in order to avoid soiling his clothes. For several weeks prior to admission, the patient complained of headaches.

Physical examination. The general physical examination revealed a fairly well-developed and well-nourished man. There was motor weakness of the left arm and leg. Left tendon reflexes were exaggerated. Left abdominal reflexes were absent.

Ocular examination. Visual acuity was:

O.D., 15/15; O.S., finger counting nasally. Hertel exophthalmometer readings with a base line of 103 were: O.D., 20; O.S., 35 (fig. 8). The right eye was wholly normal.
Fig. 9 (Grino and Billet). *Case 2*. Visual field for the right eye, March 10, 1948, 1/2,000 white; blindspot, 2/2,000 white. Visual acuity: 15/15.

The left eye showed restriction of the extraocular muscles in keeping with the proptosis. The left optic nervehead showed definite temporal pallor.

Visual field studies showed normal central and peripheral fields in the right eye, for 1/2,000, 1/330, and 2/330 white. The left eye retained only a small island of vision

Fig. 10 (Grino and Billet). *Case 2*. Visual fields, March 10, 1948: R.E., 1/330 white; 2/330 white; L.E., 10/330 white. Visual acuity: R.E., 15/15; L.E., finger counting.
nasally and below for 10/330 white. These visual field findings suggested insult to the left optic nerve probably within the orbit and not in the cranium (figs. 9 and 10).

Electrocardiography showed a right bundle branch block without activity of any

Laboratory data. Urine and blood counts were normal, as were blood urea and sugar. Wassermann was negative.

Course in hospital. On March 22, 1948, under general anesthesia, a right posterosuperior frontal craniotomy for removal of

Fig. 11 (Grino and Billet). *Case 2.* Right carotid angiography, lateral view.
Capillarogram showing the shadow of the brain tumor.

coronary lesion. Electro-encephalography showed definite electrical abnormality with concentration of disturbances anteriorly to the right of the midline. Right angiographic studies localized the cerebral tumor as a highly vascularized lesion in the right parietal region near the vertex, measuring 3 by 4 cm. Left angiography disclosed a highly vascular lesion intraorbital in location (figs. 11 and 12).

Chest X-ray films showed three oval-shaped areas of homogeneous density in the lung.

the cranial lesion was performed. The brain itself bulged quite markedly through the defect in the dura mater. The lesion was disclosed to be fluorescent due to the injection of fluorescein before the operation. The tumor was removed and frozen sections revealed a hypernephroma.

Postoperatively, the patient remained drowsy. On the first postoperative day, he developed a fever of 105°F. He died on the second postoperative day. At autopsy, the left orbital contents were obtained in a body (fig. 13).

CASE 3

History. H. was a white woman, aged 46 years, who, in November, 1947, was told by an optometrist that he was unable to correct the vision in her right eye and that she should see an ophthalmologist. The patient had no subjective complaints but on direct

Laboratory data. Hemoglobin 13 gm.; R.B.C., 4.37 million; W.B.C., 10,900 (64-percent polys, 6-percent immatures, 24-percent lymphocytes, 4-percent monocytes, 2-percent eosinophils). Urinalysis was negative. B.U.N. 13.5 mg. percent; blood sugar, 82 mg. percent; total protein, 6.4 percent.
Fig. 12 (Grino and Billet). *Case 2.* Left carotid angiography, lateral view of arterial phase. The vessels of the orbital tumor are completely filled with diodrast.

questioning admitted that, when glasses were fitted in 1945, it seemed as if the lashes of the right eye brushed against the glass and that it took numerous adjustments to fit them. She, however, had noticed no prominence of the right eye. There was no history of headache, disturbances in smell, pain in the face, or endocrine disturbance. The past history was essentially noncontributory. Examination revealed a rather obese woman with a blood pressure of 160/90 mm. Hg, but no other abnormalities (fig. 14).

Visual field studies showed normal fields for the left eye. For the right eye, there was marked peripheral contraction encroaching on the central area with marked central involvement as indicated by central field studies (figs. 18 and 19).

Eye note. Visual acuity on February 9, 1948, was: O.D., 15/30; O.S., 15/15. The right eye was more prominent than the left. Hertel exophthalmometer measurements with base-line 100: O.D., 22; O.S., 17.5. Extraocular movements were unrestricted. Fundi; O.D., showed temporal pallor and

blurring of disc margins with some fullness of veins. O.S., showed upper nasal disc margin to be blurred, slight pallor temporally, veins full.

The blindspot of the right eye could not be properly evaluated even with 20/2,000

even in the region of the optic foramen or possibly even in the orbit.

X-ray studies of the skull, including postero-anterior and lateral stereoscopic views as well as views of the optic foramina showed thickening of the right sphenoid wing and

Fig. 13 (Grino and Billet). *Case 2.* Autopsy specimen. Sagittal section of the left orbit demonstrating the tumor.

white. The right eye showed practically no field for 1/2,000 white. With 15/2,000 red, there were no definite central hemianopic features in the right eye. In the left eye, the peripheral field for 2/330 white showed no substantiating criteria for upper defect in the field. The blindspot in the left eye was within normal limits.

Dr. Chamlin thought that, in view of the complete lack of involvement, one must assume that this interference with the visual pathway was limited to the right optic nerve, probably well anterior and possibly

of the orbital roof on that side. There was suggestion of spicule formation in the latter area. Dr. Davidoff reported that the appearance was typical of right sphenoidal ridge meningioma (fig. 15). Electro-encephalograms showed an essentially normal electrical pattern.

Angiography performed by percutaneous injection of the carotid showed a distinct semilunar posterior concave depression of the anterior cerebral artery in the region of the bony overgrowth in the sphenoidal ridge on the right, at the medial termination of the

Fig. 14 (Grino and Billet). *Case 3.* Demonstrating slight proptosis of right eye.

meningioma of the outer one third of the sphenoid ridge was fairly well established and operation was recommended. The patient at first was quite resistive to the idea of surgical intervention but eventually acquiesced and was discharged to return in about one month for surgery.

On April 15, 1948, a right frontotemporal craniotomy with orbital decompression was performed under endotracheal ether anesthesia. The bone overlying the base which was markedly thickened and vascular, was rongeured away back to the anterior clinoid process, thereby unroofing the orbit. The sphenoid ridge and part of the lesser wing of the sphenoid were removed by means of perforators, burrs, and the rongeurs.

sphenoidal ridge. The venogram showed the tumor by the injection of the blood vessels. The remainder of the angiogram was considered to be within normal limits (figs. 16 and 17).

The dura was then incised and a small hemispheric tumor, measuring about 3 to 4 cm. in diameter and ½ cm. in thickness, was encountered in the dura opposite the Sylvian vessels and removed.

Course in hospital. All investigative procedures were carried out with no untoward effects. The diagnosis of a sphenoidal ridge

Fig. 15 (Grino and Billet). *Case 3.* Roentgenogram of the skull, right lateral view, showing some bony changes of the sphenoidal plate.

The orbital fascia was then incised and the orbital contents seemed to decompress themselves through the defect.

Postoperatively the patient did well and her wound healed by first intention. At the time of the patient's discharge, the visual acuity in the right eye was 15/15−2 as compared to 15/30 preoperatively. The exophthalmometer reading showed the same 5-mm. proptosis of the right eye.

of similarity. Unilateral exophthalmos and gradual loss of vision were the most prominent findings of the three, while roentgenologic changes also were present in greater or less degree in Cases 1 and 2.

That angiography has been not only useful but indispensable in making these diagnoses is evidenced by the accompanying angiograms, in which the tumors are clearly demonstrated, as well as by a close examina-
Fig. 16 (Grino and Billet). *Case 3.* Right carotid angiography, lateral view. Capillarogram showing vascular network of tumor filled with diodrast.

Pathologic report. The tumor was a meningocytic meningioma.

DISCUSSION

The three cases here presented, two orbital tumors (one primary, the other metastatic) and an intracranial tumor located at the sphenoidal wing, illustrate the difficulties in making the correct differential diagnosis in cases of unilateral exophthalmos. In spite of their different natures and locations, their histories, as well as their clinical and roentgenologic findings, show a marked degree

tion of the case histories (figs. 6, 11, 12, 16, and 17).

In Case 1, given the findings obtained by the various examinations—unilateral exophthalmos, partial loss of vision, bony changes in the sphenoidal wing of the affected side, and the aspects of the visual fields —one would suspect an intracranial lesion, which had to be ruled out. To this end, lateral and postero-anterior stereoscopic X rays of the skull were taken, as well as X rays of the optic foramina.

Although the latter were shown to be

normal, a suspicious increase in density was found at the level of the superior orbital plate and at the greater wing of the sphenoid of the affected side. An air injection behind the globe of the eye did not yield any data of diagnostic value, resulting only in marked cranial exploration (as was done in Case 2) or upon temporizing measures which could only result in further loss of vision.

Cerebral angiography was finally performed by the percutaneous method which showed unmistakably, in all three phases,

Fig. 17 (Grino and Billet). *Case 3*. Right carotid angiography, antero-posterior view, showing vascular bed of tumor filled with diodrast. The arrows point to the tumor.

ecchymosis of the eyelids, which caused the patient considerable pain and discomfort (fig. 5).

It is evident in this case that, because of inability to demonstrate an orbital tumor by the means at our disposal (angiography excepted), one would decide upon an intra-

the presence of an orbital tumor. This is one of the few cases in our series of angiographies in which general anesthesia was employed because, at that time, we were developing the percutaneous technique and we needed the maximum relaxation of the patient.

As can be seen by the angiogram (fig. 6), this tumor is eminently vascular. Although we were interested in determining its nature, we did not think that biopsy would be a safe procedure, especially in view of the untoward results of the air injection. Considering further the reluctance of the patient to accept more radical measures and the fact that a great percentage of orbital tumors are of hemangiomatous type (Reese[7]), we

toward the chiasmal area," can be easily correlated to the angiogram which shows a small number of abnormal vessels above the lesser wing of the sphenoid on the affected side.

When Case 2 was first seen by the neurosurgeon, the history (except for the nephrectomy) and the findings were almost identical to those described in the preceding case. Because a pathologic report could not be

Fig. 18 (Grino and Billet). *Case 3.* Visual fields on February 9, 1948: R.E., 2/2,000 white; L.E., 1/2,000 white. Visual acuity: R.E., 15/30; L.E., 15/15.

Fig. 19 (Grino and Billet). *Case 3.* Visual fields on February 9, 1948: R.E., 2/330 white; L.E., 2/330 white. Visual acuity: R.E., 15/30; L.E., 15/15.

agreed upon X-ray therapy and periodic examinations of the visual fields, anticipating, however, that we should have to insist upon surgical treatment, should the condition become worse.

A point of interest in this case is the relation of the ophthalmic findings to those of the angiographic. The visual fields, which suggest (in the words of Dr. Chamlin) "interference with the right optic nerve retrobulbarly, extending rather far back

obtained, the reasons for the nephrectomy were never established.

Although neither an intraorbital, nor an intracranial tumor could be ruled out on the basis of the clinical and radiologic findings alone, nevertheless an intracranial exploration was undoubtedly indicated, if only for the purpose of decompressing the optic nerve in the event that no tumor was found. This treatment would not change essentially, however strongly one might suspect the presence

of a metastasis, since we know that two different types of tumor can be present in the same individual, as has been emphasized lately by Feiring and Davidoff.[3]

Three years after the intracranial exploration, which was reported to be negative, the ocular signs were so obvious that the problem was not one of localization but of knowing the nature of the tumor. A biopsy was then performed, the report from which was "possible hemangioma."

Seven months later the patient developed a weakness on the left side of his body which was the immediate cause of his admission to Montefiore Hospital, where angiography of the left carotid system was performed in order to rule out any possible intracranial extension of the orbital tumor (fig. 12). Since this patient had neurologic signs which could be related to a possible lesion in the right cerebral hemisphere, the right carotid artery was also injected percutaneously two days afterward and a tumor was shown situated in the right frontal lobe (fig. 11).

In resume, this patient had, from the beginning, a metastatic lesion in his left orbit which was impossible to discover in its early stages and which probably could have been revealed by angiography, had angiography been available. As previously mentioned, the tumor mass removed at operation, as well as the orbital tumor obtained at necropsy, was shown to be a hypernephroma.

Case 3 had a history and presented clinical findings similar to those of the preceding cases. This patient had a unilateral exophthalmos with gradual loss of vision. Her radiologic findings, however, were compatible with an intracranial growth, showing bony changes commonly present in sphenoidal-wing meningiomas. Although the preoperative diagnosis was confirmed in the operation and was finally substantiated by the histologic report, it is evident that many doubts could have been cast upon that diagnosis without the documentary proof given by angiography (figs. 16 and 17).

More important still, from the point of view of the surgeon, was the fact that no intraorbital extension could be demonstrated angiographically. The steady improvement of the patient after the operation, in which the orbit was unroofed but not explored, testifies that no orbital tumor was present and confirms the assumption derived from the angiographic data.

At this point, we should like to mention that the absence of a tumor shadow in the angiogram does not preclude the existence of a tumor. Not all tumors have a well-developed vascular supply; astrocytomas and melanomas, for instance, are poorly vascularized and very rarely will be demonstrated by angiography. However, in these and allied cases, angiographic diagnosis is still made possible by the displacement of the vessels, as this is as much indicative of a growth as is a tumor's shadow.

However far from the scope of this paper it may seem to be, we wish to make some remarks upon the treatment of these cases, which will help to justify the emphasis that we place upon the differential diagnosis.

A complete removal of the tumor, here as elsewhere in the body, is the surgeon's aim. The removal of an intraorbital tumor or an intracranial tumor with orbital extension is, however, a major operation and not, by any means, an easy one, requiring perfect familiarity with the region, as well as knowledge of the suspected pathologic condition.

It is evident that, if the exact situation of the tumor is known and some hint of its pathology is obtained, the surgeon will be enabled to explore the intraorbital cavity with the least possible damage to the important structures that it contains.

That the removal of an intraorbital tumor by an intracranial approach is not only feasible but the route of choice in the majority of cases has been demonstrated by Cushing[1] and Dandy.[2] This approach is employed routinely by neurosurgeons. The operation consists of a frontal craniotomy, as for the

exploration of the pituitary gland, followed by the removal of the orbital roof. The capsule of the orbit is then opened widely, which allows a thorough exploration of the orbital cavity.

It is evident that one would feel reluctant to explore the orbital cavity unless the presence of a tumor were well demonstrated in advance, since the danger of damaging important structures cannot be overemphasized. Since one cannot, however, neglect such a tumor, it is of the utmost importance to have an accurate diagnosis. Although our experience is not extensive, we feel that angiography is the safest and most helpful method for differential diagnosis in cases which may show either intraorbital or intracranial tumors.

SUMMARY AND CONCLUSIONS

Two cases of orbital tumor and one of intracranial tumor are presented.

In all three cases the history and symptoms were similar.

Accurate localization was made possible by angiographic visualization of the tumors.

The importance of accurate localization as a prerequisite for proper surgical treatment is emphasized.

Cerebral angiography, by either the direct (percutaneous) or the open method, is presented as a harmless procedure, permitting radiologic visualization of orbital, as well as intracranial, tumors.

The technique of cerebral angiography is outlined.

We feel that cerebral angiography should be used in the diagnosis of cases exhibiting unilateral exophthalmos, in preference to more dangerous or less informative methods, as, for instance, pneumoencephalography, puncture biopsy, and intraorbital air injection.

A SURGICAL TREATMENT FOR PTERYGIUM BASED ON NEW CONCEPTS AS TO ITS NATURE*

H. SAUL SUGAR, M.D.
Detroit, Michigan

Although much has been written regarding the cause of pterygium, the frequency of recurrence after surgical treatment is indicative of our profound ignorance of its true nature. As a result of clinical and histologic observations begun in 1944 on military personnel, and continued since, a theory of the nature of pterygium was formulated and a new method of surgical treatment devised. The results in approximately 50 cases have been such as to warrant this communication, even though follow-up in the early military cases was not possible.

According to Kamel,[1] "a true pterygium is a pathological encroachment of part of the bulbar conjunctiva exposed in the palpebral tissue over the cornea. This encroachment is in the form of a fold of the conjunctiva, triangular in shape, with the apex, called the head, on the cornea, the base merging imperceptibly in the caruncle region or the region of the outer canthus, and the sides formed of two folds of the conjunctiva, an upper and a lower." It is considered by Duke-Elder[2] to be a degenerative process which essentially affects the cornea.

These authors, like nearly all other writers on the subject, are concerned with the cornea and conjunctiva. I believe the layer of Tenon's capsule lying in the interpalpebral zone between the conjunctiva and sclera of cornea to be the essential element in the occurrence, extension, and recurrence of true pterygium.

CLINICAL OBSERVATIONS

The first clinical observations were made on eyes with pingueculae and early pterygia to determine the relationship between the two, and the earliest onset of pterygium. It was noted that all early pterygia were associated with pingueculae and that in each instance the pinguecula was elevated sufficiently to raise the epithelium mechanically from the end of Bowman's membrane. This suggested that the latter is the barrier separating the pinguecula from corneal encroachment when it is then termed pterygium. Once the barrier had been passed, the conjunctiva appeared to be pulled onto the cornea, as shown by the fact that the pinguecula becomes the apex of the pterygium (fig. 1) and by the folding of the conjunctiva which, when released surgically, returns to the normal conjunctival position.

The view that the pterygium develops from a pinguecula was first introduced by Zehender,[3] in 1869, although Horner[4] may deserve credit for originating this theory. Fuchs[5] championed this theory and, although Hubner[6] stated that pterygium could occur independently, it is difficult to be certain of this once a pterygium of sufficient size has formed, since the pinguecula is carried onto the cornea as the head of the pterygium and may leave no evidence of its previous presence in its usual position.

Fig. 1 (Sugar). Pterygium showing vascularity and pinguecula forming its head.

OBSERVATIONS MADE DURING SURGERY

Further observations made during surgical procedures on pterygiums showed that under the conjunctiva there is a definite layer of vascularized tissue (Tenon's capsule) which, in the horizontal meridian, has the appearance of a thin muscle tendon. It continues to be the very head of the pterygium.

Histologically, this tissue contains hypertrophic and hyperplastic elastic fibers which lie parallel to each other, thus giving rise to the "tendinous" appearance. This layer separates easily from the conjunctiva and is practically free from the sclera.

In addition, some of the prominent horizontal blood vessels extending from the inner canthal region toward the head of the pterygium lie in this tissue and not in the conjunctiva itself (fig. 1). It appears that these are anterior ciliary vessels, which lie just anterior to the rectus muscles in Tenon's capsule, which are pulled across the sclera and cornea with Tenon's capsule.

Just anterior to the head of the pterygium, there is a halo of grayish-white opacity, a short distance in front of which are islands of superficial opacities that, histologically, have been found to be small vesiclelike formations in Bowman's membrane at the points where the corneal nerves pierce the latter. Fuchs[5] has described these changes well.

When the head of the pterygium is removed, it is noted that there are dense adhesions between the pterygium tissue and cornea in some parts, while in other parts the two separate easily.

HISTOLOGIC OBSERVATIONS

Aside from clinical observations, there are important histologic observations which are well known and important in formulating the theory of the nature of pterygium. Most important is the histologic similarity between the pinguecula and the body of a pterygium. Both are covered by conjunctival epithelium with variations which are not essential to the process of extension of the pterygium.

Fig. 2 (Sugar). Photomicrograph showing the dense layer of Tenon's capsule (A) and calcified areas at (B). The thin strands which lie under Tenon's capsule are seen at (C).

Near the surface of its head and neck, the pterygium is covered by flat cells, with cylindrical cells in the folds and furrows and at the base. Bowman's membrane is destroyed in places and here the superficial corneal lamellae are involved in the pterygium.

The stroma of each shows a moderately vascular areolar tissue structure, loose in the early stages and more compact later (fig. 2). There is hyaline degeneration of fibrous tissue and deposition of amorphous hyaline and sometimes chalk deposits. Hypertrophy and hyperplasia of the elastic fibers are quite prominent.

DISCUSSION

These observations have led to the following incomplete theory: A pterygium develops from a pinguecula. The latter is a degenerative change in the subconjunctival fascia (Tenon's fascia). Two factors may be significant in this degeneration.

1. The closure movements of the lids squeezing the conjunctiva between them.

2. The movements of the horizontal rectus may cause intermittent pull on Tenon's fascia. That this factor alone could not be effective is shown by the absence of these changes in the region of the vertical recti.

The degenerative process leads to hyperplasia and hypertrophy of the elastic tissue and deposition of hyaline which causes an elevation that eventually separates the epithelium from Bowman's membrane. Then, probably because of a chemotactic force either in the nature of the changes occurring when tendinous tissue attaches itself to bone or other tissue, perhaps as a response to the pull of the "tendinous" Tenon's fascia, or as a response to a nutritional demand, changes occur in the cornea adjacent to the head of the pterygium and lead to the formation of connective tissue which contracts, slowly pulling the fascial layer onto the cornea. As the process repeats itself the tissue encroaches further onto the cornea, pulling the conjunctiva with it.

This theory explains the recurrences produced by all methods of pterygium surgery in which the subconjunctival tissue is permitted to remain.

This theory considers pterygium to be a purely degenerative process. On the other hand, Kamel believed the process to be inflammatory and D'Ombain[7] held that it is an irritative disease due to exposure and not primarily a degeneration, but he stressed that it is secondarily a degeneration. Kamel felt that a keratoconjunctivitis occurs, with the laying down of fibrous bands which contract and cause encroachment of conjunctiva onto the cornea. He treated pterygium by separating the conjunctiva from the underlying layer and cauterizing subconjunctivally with phenol on a toothpick.

New surgical procedure

On the basis of the theory herein presented, the following surgical procedure has been used successfully. No recurrence has been seen. None is expected, since the operation is based on the formation of a scleroconjunctival adhesion, 4-mm. wide adjacent to the limbus.

Anesthesia is induced by the use of 2 or 3 installations of 4-percent cocaine-hydrochloride solution at 2-minute intervals. Then,

a small amount of 2-percent procaine solution, enough to raise a thin bleb between the sclera and Tenon's capsule, is introduced through a hypodermic needle beneath the body of the pterygium about 4 to 5 mm. from the limbus.

Incision. After about five minutes, an incision (fig. 3) is made in the conjunctiva just posterior to the head of the pterygium, extending all the way from its lower to its upper border and then laterally at each border to the limbus.

This incision separates the conjunctiva from the cornea and permits tthe entire conjunctiva, forming the surface of the pterygium, to be undermined to the plica semilunaris, and to a couple of millimeters beyond its upper and lower borders. The conjunctiva is thus freed from attachment to the subconjunctival layer and may resume its normal position.

A second incision is now made at the same location as the first, this one being made through the "tendinous" layer of the Tenon's capsule tissue, from the lower to the upper border of the pterygium at this point.

A scissors is inserted between this layer and the cornea and sclera, and this layer is undermined for about 4.5 to 5.5 mm. from the limbus, and extending about a millimeter beyond the upper and lower borders of the pterygium. The portion of Tenon's capsule, which is thus undermined, is excised.

The head of the pterygium is now shaved from the cornea in such a manner as to remove as much of the scar tissue as possible, leaving the limbus free.

Suture. A double-armed silk suture is inserted through the superficial layers of the sclera about 3.5 mm. from the limbus and parallel to the latter, and each end is passed through the conjunctiva near its cut edge. The suture is tied over the conjunctiva, leaving a bare area of 3 mm. between the cornea and conjunctiva.

A patch is applied. Ointments are used after the first day. The suture is removed on the fourth day. The suture may be dis-

pensed with if the surgeon desires. This tends to lessen the tissue reaction considerably.

Comment. This procedure is simple enough to be done in the office, if adequate facilities for sterility are available. It is surgically sound as compared to the Mc-Reynold's operation, in which epithelium is

buried. The eye becomes pale much more quickly than with any operation in which the subconjunctival tissue is permitted to remain. The formation of the adhesion between the conjunctiva and sclera and the epithelization of the bare area are rapid.

In some cases, an adhesion of conjunctiva to the area of corneal scar, where the head of the pterygium had been, gives the impression of recurrence, but this has not been observed to continue further onto the cornea.

There has recently appeared another pterygium operation based on similar principles (D'Ombain[7]). In fact, it has been the stimulus of D'Ombain's paper which has led to the actual writing of this one.

In his procedure, the entire subconjunctival tissue is removed between the cornea and the plica semilunaris and a 5-mm., bare area of sclera left to epithelize the unsutured conjunctival edge. This procedure should lead to good results but has the disadvantage of possible injury to the horizontal rectus muscles while removing the Tenon's tissue since the internus inserts only 5.5 mm. from the limbus.

CONCLUSION

A theory is presented that the development of pterygium from pinguecula is a degenerative process in which the hypertrophic and degenerative changes in Tenon's capsule in the interpalpebral zone are considered to play the essential part. A simple, effective operative procedure based on this theory is presented.

RETROLENTAL FIBROPLASIA IN PREMATURELY BORN CHILDREN*

ANITA PEEK GILGER, M.D.
Cleveland, Ohio

The purpose of this study was twofold. The first was to determine the incidence of retrolental fibroplasia in prematurely born children, together with any factors in the development of the disease which such a survey might unearth. The second purpose was to attempt to gain a better knowledge of the clinical course of this condition by observing a group of prematurely born infants at regular intervals from birth.

Terry[1] stated that there was an apparent variation in the frequency of retrolental fibroplasia in different medical centers. It was, therefore, decided to conduct a survey in a middle-western community. In 1945, Terry[2] stated that Clifford had found in a series of less than 50 infants at the Boston Lying-In Hospital an incidence of retrolental fibroplasia of 12 percent in infants weighing 1,307 gm. or less at birth. In 1948, Clifford and Weller[3] quoted Allers as saying that 23 percent of the infants weighing between 2 to 3 pounds at birth, at the same hospital, develop retrolental fibroplasia. William and Ella Owens[4] found, in premature infants born between 1945 and 1947 at The Johns Hopkins Hospital, 5 cases of retrolental fibroplasia in 83 observed cases with birth weights of 1,899 gm. or less, an incidence of 6 percent.

Reese[5] states that there has been an apparent increase in retrolental fibroplasia in the last few years. This may possibly be due to improved survival of the babies whose birth weights were 1,814 gm. or less. He also states that 40 to 60 percent of the mothers of his patients with retrolental fibroplasia gave a history of uterine bleeding during pregnancy.

Vitamin A as a possible etiologic factor has been considered since Warkany[6] found a fibrous retrolenticular membrane in place of the vitreous in rats with maternal vitamin-A deficiency. Clifford and Weller[3] state that in their series of cases, the postnatal administration of absorbable, water-soluble vitamin A did not prevent the later development of retrolental fibroplasia.

Bakwin[7] suggested the possibility that retrolental fibroplasia was sex-linked because, out of 150 patients reported by Reese and Terry, 95 were males. Krause[8] described retrolental fibroplasia as a part of a congenital encephalo-ophthalmic dysplasia of unknown origin. He stated that, if the child was examined after the age of four years, the ocular disease rarely occurred without clinical signs of involvement of the brain.

METHOD

This survey included 229 children with a birth weight of less than 2,268 gm. (5 pounds) who were either born at, or admitted before the age of 24 hours to, the Cincinnati General Hospital during the 5-year period from January, 1943, to January, 1948. None of the infants born during this period was a private patient. Form letters or appointments on hospital discharge, seconded by home visits of public health nurses, were the methods of inducing the parents to bring the children to the clinic.

For a 6-month period, from July, 1947, to January, 1948, every infant born in the hospital weighing less than 2,268 gm. was examined within the first week of life and every week to two weeks thereafter during the hospital stay. After discharge, the babies of this group whose parents coöperated were examined at monthly intervals until the baby became at least six months of age.

In addition to this group, children born between January, 1943, and July, 1947, were

examined; but only one clinic visit was made and that at a time when the child had attained the age of one year or more.

In every case, examination consisted of inspection of the external segment of the

INCIDENCE

In the 5-year period, 1943 to 1948, there were 507 babies born at the Cincinnati General Hospital weighing less than 2,268 gm. at birth and presumably living at the

TABLE 1

INCIDENCE OF RETROLENTAL FIBROPLASIA IN PREMATURE CHILDREN

eyes and ophthalmoscopic examination following pupillary dilatation with either homatropine hydrobromide or neosynephrin hydrochloride (ophthalmic). Other examinations were performed as indicated. With very rare exceptions, the only sedation required for satisfactory examination of the infants was either formula or glucose water.

time of this study (table 1). Of this total, 156 weighed 1,814 gm. (4 pounds) or less. Of the total group, 229, or 45.2 percent, were examined; 96, or 61.5 percent of those with birth weights of 1,814 gm. or less were seen.

This higher incidence of returns was probably not due to the greater concern of the mothers of the smaller babies but to the

fact that in the lower-weight group repeated nurse visits or telephone calls were made when appointments were broken, a follow-up which time and personnel did not permit for the higher weight group. Of the total group, 112 or 22.1 percent had moved away from the Cincinnati or the post-office area and nurses had lost their addresses at the time of the study. The remaining 32.7 percent could not be persuaded to come to the clinic.

Retrolental fibroplasia occurred in 7 patients out of the total of 229 seen, an incidence of 3.1 percent. However, the disease was not seen in any children whose birth weights were above 1,814 gm. Its incidence in the 96 with birth weights of 1,814 gm. or less, who were examined, was 7.3 percent.

These percentages of incidence of retrolental fibroplasia are probably higher than they would have been if it had been possible to examine all the children available in the Cincinnati area. Of the children with birth weights of 1,814 gm. or less, there were 29 unobserved children, or 18.6 percent who were living within the Cincinnati area at known addresses at the time of the study and whose mothers received a minimum of two appointments which were broken.

These mothers had been visited by public health nurses who usually saw the children and reported no obvious gross defects of the eyes. Although it is impossible to exclude the existence of retrolental fibroplasia merely by external examination, it is unlikely that any of the 29 unexamined children had such an extensive retrolental membrane that the undilated pupillary area appeared white. If this hypothesis were taken to be true, the incidence of retrolental fibroplasia in the babies weighing 1,814 gm. or less at birth would be close to 7 out of 125, or 5.6 percent.

Of the 7 cases of retrolental fibroplasia, 2 had birth weights of less than 1,361 gm. (3 pounds) and 5 had birth weights between 1,362 and 1,814 gm. (table 2). In this study the data failed to reveal any significant difference in incidence between these two weight groups.*

TABLE 2

2,200–2,268	27	0

Total 229

Although it may seem from Table 1 that the increase in incidence of retrolental fibroplasia from 0 to 11.8 percent in the lower weight group during the 5-year period of this study is significant, this is not the case. When a division of the examined prematures with birth weights of 1,814 gm. or less into later and earlier cases with respect to birth dates is made, the earlier half, or 48, had one case of retrolental fibroplasia; whereas, the latter half had 6 cases ($X^2 = 2.459$; $P = > 0.10 < 0.20$).

ETIOLOGIC FACTORS

In considering possible pre- and postnatal events which may affect the development of retrolental fibroplasia, only the smaller prematures (1,814 gm. or less) were investigated. This was done not only because of the fact that it was only in this group that the disease developed, but also because the heavier weight group was usually discharged from the hospital before the age of one week so that statistics concerning postnatal management and care would be dependent upon maternal memory.

---

* Statistical significance has been determined in this study by the method of Chi square, using four-cell contingency tables wherever possible. Yate's correction was used in all four-cell contingency tables with small frequencies.

SURVIVAL RATES

The investigation of a possible increased survival rate in recent years of the smaller premature infants falls into two groups: (1) Survival of prematurely born infants to the time of discharge from the hospital, and (2) survival after hospital discharge to the age of six months or one year, by which time weights are broken down into three groups, it is found that the group of children with birth weights between 1,362 and 1,814 gm. does have a statistically significant increase of survivals to hospital discharge ($X^2 = 15.447$; for $n = 4$, $P = < 0.01$).

In Table 4, the known survival rate from hospital discharge to one year of age is

TABLE 3

SURVIVAL TO HOSPITAL DISCHARGE OF PREMATURES WITH BIRTH WEIGHTS OF 1,814 GRAMS OR LESS

the existence of retrolental fibroplasia could be determined.

The rate of survival to discharge from the hospital for the 5-year period, 1943 to 1948, is shown in Table 3. Only liveborn premature infants are included, evidence of life being heart-beating or breathing. The percentage of living babies weighing 1,814 gm. or less increased from 29.1 percent in 1943 to 51.7 percent in 1947. This is not statistically significant but is suggestive that further analysis of the figures might show some significance ($X^2 = 12.310$; for $n = 4$ $P = > 0.01 < 0.02$). When the birth

shown. Those cases listed as surviving have been seen either by me or a public health nurse, or in a Babies' Milk Fund Association Clinic after the age of either six months or one year had been attained. Out of 162 discharges, 22, or 13.6 percent of the children either were lost or had moved out of the Cincinnati area before the age of one year. Only 6 or 4.3 percent of the children not lost are known to have died during the first year of life.

PRENATAL INFLUENCES

Because the observed infants who later

developed retrolental fibroplasia had normal eyes when seen in the first week of life, it has been said that the causative factor or factors would be more likely to occur during postnatal rather than prenatal life. However, the maternal histories of prematures with birth weights of 1,814 grams or less were studied for possible clues.

In Table 5, the history of bleeding prior to onset of labor is given for mothers of ob-

served smaller prematures in the 5-year period of the study. Bleeding varied in degree from spotting to an amount requiring hospitalization and transfusion. Slight bleeding occurring at the onset of labor was not considered abnormal. The one case of retrolental fibroplasia with maternal bleeding had only two episodes of staining. In the observed group not having retrolental fibroplasia, 19.8 percent of the mothers gave a history of bleeding during pregnancy, while in the group with retrolental fibroplasia, the figure was 16.7 percent. The difference in incidence of bleeding between the two groups is not statistically significant.

The following conditions which may have something to do with the production of normal eyes or eyes with retrolental fibroplasia were studied, but the figures failed to reveal any statistically significant differences.

1. Age at delivery
2. Parity

that the difference between normal eyes and those with retrolental fibroplasia is due to any factor other than chance becomes even less than when the causes are grouped into known and idiopathic.

POSTNATAL AND OTHER FACTORS

It has been stated that the factor (or factors) causing retrolental fibroplasia probably occurs in early postnatal life. The smaller premature infant is placed in an environment which, in spite of pediatric advances in handling, is far different from the optimum which would have been maintained in utero.

In general, the smaller prematures in this study received similar management. The policy in the premature nursery has been one of adapting treatment, such as the administration of intravenous and subcutaneous fluids, to the individual case rather than one of following a routine procedure. The environment, method of regulation of temperature and humidity, and administration

[*] Mothers of observed prematures with birth weights of 1,814 gm. or less, 1943 to 1948.

of oxygen and carbon dioxide have remained essentially the same during the 5-year period.

During the last three years, the diet has been changed from a usual one of breast milk or evaporated milk to a usual one of a formula relatively high in protein and low in fat according to the principles of Levine and Gordon.[9] The factor of type of diet showed no statistical significance between normal and retrolental fibroplasia cases.

During the last three years, increased amounts of vitamin K were administered following birth, but this also showed no statistically significant difference.

The infants routinely received a minimum of 2,000 units of oil-soluble vitamin D and a minimum of 100 mg. of ascorbic acid per day during their hospital stay. Neither spe-cific medications nor the presence or absence of recognized illness during the hospital stay showed statistically significant differences. Three differences occurred, however, which warrant more detailed report.

VITAMIN A

Most of the infants received added vita-min A during their hospital stay. However, from May through December, 1947, water-soluble vitamin D without vitamin A was given. The only vitamin A these babies re-ceived was that included in the formula, ap-proximately 590 units per day. This is less than the amount sometimes considered a minimum, although the actual requirements of vitamin A in the prematurely born infant are unknown.

Only the first month of life is considered in Table 6, since most of the babies had been discharged from the hospital before the age of two months. The choice of considering seven days as a dividing line was made because vitamin-A stores in the body are not so rapidly lost as are some other vitamins.[10]

TABLE 6

RELATIONSHIP OF VITAMIN A ADDED IN FIRST MONTH OF LIFE TO RETROLENTAL FIBROPLASIA IN PREMATURES WITH BIRTH WEIGHTS OF 1,814 GRAMS OR LESS, 1943 TO 1948

	Vitamin A Added 7 Days or More	Vitamin A Added 6 Days or Less*	Total
Normal	56	33	89
Retrolental Fibroplasia	1	6	7
Total	57	39	96

$X^2 = 4.4635$; $P = > 0.02 < 0.05$.
* In this group 30 prematures received no added vitamin A during the first month of life. The remaining three received oil soluble vitamin A as follows: (1) normal male, on the 30th postnatal day; (2) normal female, from the 26th to 30th postnatal day; and (3) male with retrolental fibroplasia, from the 27th to 30th postnatal day.

It could be expected that the administration of vitamin A for only seven days in the first part of the month would provide vitamin A for use in the body during the rest of the month. The difference in incidence between the groups given and not given additional vitamin A is not statistically significant.

All of the observed prematures in the series, who received vitamin A, were administered it in the oil-soluble form. Consequently, no comparison in results could be made between those receiving water-soluble and oil-soluble vitamin A.

SEX

In this survey, in the group of observed prematures with birth weights of 1,814 gm. or less 45.8 percent were males. Every case of observed retrolental fibroplasia was in a male. The predominance of the development

TABLE 7

RELATIONSHIP OF SEX TO OCCURRENCE OF RETROLENTAL FIBROPLASIA IN PREMATURES WITH BIRTH WEIGHTS OF 1,814 GRAMS OR LESS, 1943 TO 1948

$X^2 = 6.72$; $P = < 0.01$.
Identical twins were included in the table since affection of only one twin has been known. Only two pairs of identical twins, one boy and one girl, were observed in this weight group. If one member of each of these pairs is omitted, $X^2 = 6.77$; $P = < 0.01$.

of the disease in males in this study is statistically significant (table 7).

During the 5-year survey, only two prematures, both males, were administered testosterone (as an aid to bone maturation). Of these two, one developed retrolental fibroplasia and the other did not. Two cases are an insufficient foundation on which to draw any conclusions as to the role of testosterone. However, because of the fact that statistics indicate that retrolental fibroplasia is sex-linked, further investigation of the results of testosterone administration to prematures is indicated.

When the numbers of male prematures receiving additional vitamin A for seven days or more during the first month of life are compared with those who received less, the difference in incidence of retrolental fibroplasia is found to be not significant statistically (table 8).

TABLE 8

RELATIONSHIP OF ADDED VITAMIN A TO RETROLENTAL FIBROPLASIA IN MALE PREMATURES*

	Vitamin A Added 7 Days or More	Vitamin A Added 6 Days or Less	Total

* All children included had birth weights of 1,814 gm. or less and were less than four years of age at time of examination.

ASSOCIATED INTRACRANIAL DISEASE

Dr. James Fisher[11] examined an unselected portion of the observed children with birth weights of 1,814 gm. or less and compared them with the Yale Developmental Scale. All were less than four years of age. His results are shown in Table 9. Only 1 of the 5 children with retrolental fibroplasia whom he examined was mentally retarded. The difference between the normal cases and the retrolental fibroplasia cases is not statistically significant in this group.

REPORT OF CASES

After a retrolental membrane has developed to its final extent and especially after the eye has become phthisical, it is difficult, clinically, to distinguish this condition from other pathologic conditions. Furthermore, at these stages the appearance may offer false or no clues as to the preceding course of events. Since routine ophthalmoscopic examinations from the time of birth to the development of retrolental fibroplasia have rarely been made, the descriptions of three cases are given in detail.

The normal eye in a newborn infant is very different in appearance from eyes of children who have reached the age of one year. Pigmentation, with the exception of most Negro babies, is usually clinically absent so that the irides are a grayish "infant" blue, and choroidal vessels are prominently seen in a reddish, hazy fundus. Discs have either no cupping, or slight elevation due to the presence of Bergmeister's papilla, and they are usually a dead-white in color. Disc margins are frequently not distinct. The macula is not discernible until about the fourth postnatal month; this time is usually the same in prematurely born and full-term infants. Depending on the degree of prematurity, various degrees of persistence of the fetal vascular system are seen; in most cases these atrophy completely in the course of time.

CASE 1

History. This Negro boy, born on July 15, 1947, had a birth weight (at one-half hour of age) of 1,715 gm. (3 lbs. 12½ oz.). The mother, aged 25 years, had two full-term, normal living children, aged 6 and 7 years.

On June 4, 1947, she was admitted to a tuberculosis sanitarium with far-advanced tuberculosis of the lungs. During the pregnancy she had no history of uterine bleeding or virus infection. Kahn and Hinton serologic tests were negative, and she denied history of syphilis. She had no chronic illness other than tuberculosis. Delivery was precipitous and occurred after an estimated 7-month gestation. The mother died from tuberculosis 12 days after the birth of the baby.

The baby had no recognized illnesses during his hospital stay. Management was routine except that he received no vitamin A other than that contained in his formula for the first two months and evaporated milk for the remainder of his stay. He was discharged at the age of 3 months, 18 days, with a weight of 4,370 gm.

Eye Examinations. (Aged 10 days). External. O.U.: Lids, lacrimal apparatus, conjunctivas, corneas, pupillary size and reaction to light, and scleras were normal. Horizontal corneal diameters were 8.5 mm. Irides were pigmented.

Ophthalmoscopic. O.U.: Atrophic tags of the pupillary membranes were present. There was a good red reflex everywhere. The discs were pale, without cupping, and the margins were slightly blurred. No remnants of the hyaloid artery or tunica vasculosa lentis were seen. The retinas showed very early pigmentation. The retinal vessels were normal. There was no evidence of any retrolental fibrous tissue.

(Aged 3 weeks). External. O.U.: No change. Ophthalmoscopic. O.U.: The disc margins were now distinct, although there was no pigment outlining them. Otherwise no change.

(Aged 5 weeks). External. O.U.: No change. Ophthalmoscopic. O.U.: The color of the discs was now a normal pink and slight cupping could be seen. There was a slight increase in the retinal pigmentation. The retinal vessels, both arteries and veins, had become very tortuous; in the midperiphery many were corkscrew in shape. No aneurysmal dilatations were seen.

Since tortuosity of the retinal vessels is seen in

sickle cell anemia, a sickling preparation was made; there was no sickling.

(Aged 2 months, 11 days). External. O.U.: There was no change except for a possible faint whitish sheen in the pupillary area behind the lens.

Ophthalmoscopic. R.E.: With a plus 8D. lens, a pinkish gray tissue containing many fine blood vessels was seen in the lower half of the eye. This tissue had the clinical appearance of a detached retina. At the 6-o'clock position, projecting anteriorly from this tissue, there was a bright-red area of fresh hemorrhage. Above there was a gray area, which appeared to be thickened retina rather than detached retina; in this area no vessels could be seen, but the vitreous was hazy, obscuring it.

L.E.: Except for the area from the 10- to 12-o'clock positions a pinkish gray tissue could be seen behind the lens. From the 6- to 10-o'clock positions this was most clearly seen with a plus 10D. lens. The remainder was best seen with a plus 7D. lens. The tissue contained fine blood vessels and many fresh small hemorrhages. From the 10- to 12-o'clock positions, a gray tissue could be distinguished with a plano lens; the vitreous over this area was hazy. The interpretation was the same as that made for the right eye—thickened retina from the 10- to 12-o'clock positions and detached retina elsewhere.

In neither eye could the discs be seen. No elongated ciliary processes were seen. Tension to fingers was within normal limits. Tension was (local anesthesia, baby not crying): R.E., 25 mm. Hg with 5.5 gm. weight; L.E., 22 mm. with a 5.5 gm. weight (Schiøtz). The vessels of the retrolental membrane were not tortuous.

(Aged 3 months). External. O.U.: No change.

Ophthalmoscopic. R.E.: With a plus 10D. lens, there was a gray tissue containing fine blood vessels and old and fresh hemorrhages everywhere just behind the lens. L.E.: In the far periphery at the 8-o'clock position there was a little normal-appearing retina. Elsewhere there was a grayish vascularized tissue with fresh and old hemorrhages.

(Aged 3 months, 2 weeks). External. R.E.: For the first time a grayish white tissue with a few hemorrhages could be definitely distinguished filling the pupillary space behind the lens. L.E.: No change.

Ophthalmoscopic. R.E.: There had been no change except that the retrolental tissue had become whiter and appeared to be thicker. L.E.: The entire retina appeared to be detached, but the vitreous was so cloudy that details could not be seen.

(Aged 4½ months). External. R.E.: Tension to fingers was softer than normal. The pupil was bound down by a white secondary pupillary membrane with an irregular surface and could not be dilated with neosynephrin. L.E.: No change.

Ophthalmoscopic. R.E.: Examination could not be made. L.E.: Temporally, at the 9-o'clock position there was a grayish white tissue elevated 10 diopters. The vitreous was less hazy so that some retinal details could be distinguished. The retina was seen with a plus 1D. lens. The retinal vessels seen were not tortuous. On the surface of the

retina extending forward into the vitreous, there were grayish white areas resembling either glial or connective-tissue proliferation. There were many fresh preretinal hemorrhages.

(Aged 5½ months). External. R.E.: In the center of the cornea there was a dense white opacity about 1.5 mm. in diameter. There was iris bombé. Tension to fingers was mushy soft, and the pupil would not dilate because of the secondary pupillary membrane. L.E.: No change.

Ophthalmoscopic. L.E.: The vitreous was so cloudy that undetached retina, if present, could not be visualized. There was an old hemorrhage behind the lens.

The foster mother reported that there were transient episodes of redness of the right eye during which time the baby would rub his eye and cry. At no time while the baby was under my observation was there either conjunctival injection or positive aqueous ray.

(Aged 7 months). External. Horizontal corneal diameters were 9.5 mm. A moderately rapid searching nystagmus had developed. R.E.: The corneal opacity had enlarged. Otherwise there was no change. L.E.: Tension to fingers was soft. Otherwise no change.

Ophthalmoscopic. L.E.: The vitreous was still very cloudy.

(Aged 8 months). External. R.E.: The corneal opacity was 5 mm. in diameter. In the upper temporal quadrant of the iris there was a brush of newly formed dilated vessels. L.E.: White tissue could be seen in the pupillary area. There was no pupillary reaction to light.

Ophthalmoscopic. L.E.: There was no red reflex. The dense white triangle of tissue at the 9-o'clock position was persisting. Elsewhere there was a grayish-white tissue elevated 10 diopters and containing fine blood vessels. A complete retinal detachment appeared to have occurred in this eye also.

The baby was sent to Boston to a home for preschool blind children. He was moderately retarded physically and mentally.

CASE 2

History. This white boy, born on November 3, 1947, had a birth weight of 1,715 gm. (3 lbs. 12½ oz.). The mother was aged 34 years at the time of delivery. She had one full-term, normal child, aged 5 years.

During this pregnancy she had had staining twice, once in the third month and once a week before the onset of labor. She had no history of virus infection, chronic disease, or syphilis. The Kahn test was negative. Labor occurred spontaneously at the end of an estimated 7½-month period of gestation, was of 3 hours' duration, and presentation was right occipito-anterior. There was no known cause for the premature onset of the labor.

At birth, the left side of the baby's face appeared bruised and blue. One week after birth the infant had a moderate jaundice. He had had a fracture of his 7th rib in delivery. On December 13, 1947, the baby developed gastro-enteritis due to an un-

known cause. The baby's management during his hospital stay was routine with the exception that he received no added vitamin A, other than that in his formula. He was discharged at the age of 2 months, 11 days, with a weight of 2,325 gm.

Eye Examinations. (Aged 3 days). External. O.U.: Lids, lacrimal apparatus, and conjunctivas were normal. Corneas were very slightly cloudy, probably due to silver nitrate administered at birth. Irides were an "infant" blue, or unpigmented. Pupillary size and reaction to light and scleras were normal.

Ophthalmoscopic. O.U.: Nonpatent pupillary membranes with three arcades were present. There was a good red reflex everywhere. Discs were the same shade as the retina which was clinically unpigmented. Disc margins were very indistinct, and there was no cupping. Retinal vessels were normal. No retinal hemorrhages, remnants of hyaloid artery or posterior tunica vasculosa lentis, or abnormal retrolental tissue were seen.

(Aged 2 weeks). External. O.U.: The corneas were quite clear. Otherwise no change.

Ophthalmoscopic. O.U.: The pupillary membranes had atrophied considerably so that only a portion of the first layer of arcades was well developed. Otherwise no change.

(Aged 1 month). External. O.U.: No change. Ophthalmoscopic. O.U.: Pigment was developing in the fundus so that the choroidal vessels were no longer plainly seen except in the periphery of the fundus. Otherwise no change.

(Aged 2 months). External and ophthalmoscopic. O.U.: No change.

(Aged 3½ months). External. O.U.: No change. Irides were blue but had lost their grayish, "infant" blue appearance. Tactile tension was normal. The anterior chambers were of normal depth, and no iris synechias were present.

Ophthalmoscopic. O.U.: The pupillary membranes had not changed in appearance. Nasally, in both eyes, there was a retrolental gray tissue containing small blood vessels and elevated 10 diopters. There were no hemorrhages on the surface of this membrane which extended over a fourth of the eye and appeared to be detached retina. Elsewhere there was a poor red reflex, but vitreous opacities inhibited a detailed examination of the retina. No elongated ciliary processes were seen.

(Aged 4 months). External. O.U.: No change. The corneas were 8.5 mm. in horizontal diameter. Ophthalmoscopic. O.U.: The nasal retrolental membranes had extended to the midline. Temporally, there was no membrane, but vitreous cloudiness obscured fundus details. Otherwise no change.

(Aged 4¾ months). External and ophthalmoscopic. O.U.: No change.

(Aged 5¾ months). External. O.U.: The retrolental membranes could be seen by focal illumination. Ophthalmoscopic. O.U. There had been a little clearing of the membrane in the far nasal periphery of the right eye. Otherwise no change.

(Aged 7 months). External and opthalmoscopic. O.U.: No change.

(Aged 7¾ months). External. O.U.: The baby usually held his eyes in a depressed position, but had no searching nystagmus. Both pupils reacted to light. Otherwise no change. Ophthalmoscopic. O.U.: No further change. Vitreous cloudiness persisted.

The baby's mental development was normal. He had still not attained the physical development of a full-term infant of comparable age.

CASE 3

History. This Negro boy, born November 23, 1947, had a birth weight (at one-half hour of age) of 1,086 gm. (2 lbs. 6 oz.).

The mother, aged 27 years, had had one abortion and had one full-term, normal daughter, aged 2 years. During this pregnancy she had no uterine bleeding or virus infections. In 1946, she was told that she had syphilis and she had 60 injections during that year. Her Kahn test was negative during this pregnancy, and there was no evidence of syphilitic infection of this baby. The mother had no other chronic diseases. Labor and delivery occurred spontaneously outside the hospital, after a 5½-month gestation, as estimated by the mother.

The baby was admitted to the hospital at the age of one-half hour. His development was poor; in the first month he gained only one ounce over his birth weight. On January 27, 1948, he developed atelectasis due to bronchial obstruction of right upper and lower lobes. Suction of the trachea and bronchi caused marked improvement.

His management was routine with two exceptions. From November 24th to December 20th he received testosterone (2.5 mgm., twice daily). He did not receive vitamin A, other than that contained in his formula until he was 49 days old. He was discharged at the age of 2¾ months with a weight of 2,380 gm.

Eye Examinations. (Aged 1 day). External. O.U.: Lids, lacrimal apparatus, conjunctivas, corneas, pupillary size and reaction to light, and scleras were normal. Irides were pigmented.

Ophthalmoscopic. O.U.: Completely formed pupillary membranes persisted. There was a good red reflex everywhere through dilated pupils. Detailed fundus examination was postponed, since the baby was in very poor condition.

(Aged 2 weeks). External. O.U.: No change. Ophthalmoscopic. O.U.: The pupillary membranes had atrophied slightly. A good red reflex was present everywhere. The discs were pale with no cupping but with distinct margins. The fundi were not clinically pigmented. Retinal vessels were normal. The maculas had not yet developed. No remnants of the hyaloid artery, or posterior tunica vasculosa lentis, or retrolental fibroplasia were seen.

(Aged 1 month). External and ophthalmoscopic. O.U.: No change except for further atrophy of the pupillary membranes.

(Aged 1 month, 2 weeks). External and ophthalmoscopic. O.U.: Fundi were pigmented. Otherwise no change.

(Aged 2 months). External and ophthalmoscopic. O.U.: Only slight tags of the pupillary membrane remained. Otherwise no change.

The patient's first appointment for examination after discharge and several others were broken because of his mother's illness; so he was not seen as frequently as desired.

(Aged 4½ months). A public health nurse had noticed an occasional nystagmoid movement the preceding week.

External. O.U.: No change. Horizontal corneal diameters were 10 mm. Pupillary size and reaction to light were normal. Anterior chambers and tactile tension were normal.

Ophthalmoscopic. R.E.: The pupillary membrane remnants had completely atrophied. There was a good red reflex everywhere. The disc had distinct margins, good color, and a little cupping. The macula had developed and was normal. Vessels and peripheral retina were normal. No retrolental membrane was present.

L.E.: Pupillary membrane remnants had atrophied. In the far temporal periphery behind the lens, there was a crescent-shaped hemorrhage bounded posteriorly by retinal detachment about one-half disc diameter in width and 10 diopters in elevation. Elsewhere, there was a good red reflex. The vitreous was clear; disc and retina were as in the right eye. The retinal vessels were not tortuous.

(Aged 6 months). The mother stated that she had been noticing a difference in the size of the two eyes.

External. O.U.: The horizontal corneal diameter of the right eye was 11 mm.; that of the left, 10 mm. Otherwise no change.

Ophthalmoscopic. R.E.: No change; normal. L.E.: In the far temporal periphery, hemorrhage was still present. The detached retina had become white in color, as if fibrosis and thickening had occurred, but the extent of the detachment had increased only slightly. The vitreous was still clear. Temporally, the retina contained many white streaks. The retinal vessels were not tortuous. The disc and nasal retina were normal.

(Aged 6½ months). External. O.U.: The left pupil did not react to light, but the right did.

Ophthalmoscopic. R.E.: No change. L.E.: The vitreous had become slightly cloudy. The temporal retinal detachment had increased. Temporally up to the disc, the retina was wrinkled and elevated 2 to 3 diopters. The nasal periphery was normal.

The mental and physical development of this infant was normal.

DISCUSSION

The incidence of retrolental fibroplasia in this study appears lower than that found in Boston; however, since the percentage incidences of the Boston groups are the only figures cited, a statistical comparison cannot be made. A comparison with the incidence found by Dr. William and Dr. Ella Owens in Baltimore shows almost identical findings. In their observed cases with birth weights of 1,899 gm. or less, the incidence of retrolental fibroplasia was 6.0 percent. In this study, 7 cases of retrolental fibroplasia were found in 114 examined cases with birth weights of 1,899 gm. or less, an incidence of 6.1 percent (table 2. $X^2 = 0.00131$; $P = > 0.98 < 0.99$). In the observed groups in Baltimore and Cincinnati, the incidence of the disease is the same.

At the Cincinnati General Hospital there was a statistically significant increase in survival to hospital discharge of prematures with birth weights between 1,362 and 1,814 gm. from 1943 to 1948. However, this was not accompanied by a statistically significant increase in the number of cases of retrolental fibroplasia for the same period of time.

The incidence of retrolental fibroplasia in children given and not given additional vitamin A in the first month of life is not statistically significant in this study. However, since the probability of the observed difference being due to chance is less than 0.05, the figures indicate that a conclusive statement that vitamin A does not play a role in the development of retrolental fibroplasia in this study cannot be drawn.

The fact that in this survey more boys than girls developed retrolental fibroplasia is statistically significant. It evokes the question as to whether or not testosterone should be administered to prematurely born infants for therapeutic purposes.

Other possible etiologic factors were studied but were not found to have differences which were statistically significant. These factors were: uterine bleeding during pregnancy, age and parity of mother at delivery, occurrence during pregnancy of virus infections or chronic illness, cause of premature onset of labor, race, associated intracranial disease, vitamin A received by boys and early postnatal management and course other than those factors previously discussed.

The three cases of retrolental fibroplasia followed from birth have the following noteworthy findings:

1. External and ophthalmoscopic examinations of each baby during the first two weeks of life revealed no findings varying from those usually seen in the normal newborn premature infant. It is possible that at the very extreme periphery of the retina some pathologic process may have been present at birth. However, from the succeeding events this possibility would seem highly unlikely.

2. None of the three infants had a hyaloid artery or posterior tunica vasculosa lentis or their remnants present after the first two weeks of life. The cases observed from birth are too few to exclude the development of retrolental fibroplasia in eyes in which the hyaloid artery or posterior tunica vasculosa lentis or their remnants persist; however, it does exclude the suggested[2] role of these fetal vessels as structures producing the development of retrolental fibroplasia.

3. In one case, the first indication of any abnormality was the development of considerable tortuosity of the retinal vessels. The clinical appearance may resemble that seen in von Hippel's disease.

4. In each case, preceding the development of a retrolental membrane, elevation and detachment of the retina occurred. In two cases, hemorrhages were present on the surface of the detached retina, probably indicating some vascular disorder. After retinal detachment had persisted, the eye became white in appearance instead of gray, as if a little fibrous tissue had developed. The sequence of events in these cases seems to indicate that the retina is primarily involved in the formation of the membrane rather than secondarily involved, which was the earlier conception.[12, 13]

5. In all three cases varying degrees of vitreous cloudiness were observed. This may indicate the existence of an underlying retinitis or choroiditis.

6. In no cases, except after the development of shallow anterior chambers, synechias, and glaucoma, was there any injection of the conjunctival vessels or positive aqueous ray. This would seem, in the three followed cases, to indicate the absence of an anterior uveitis in the development of retrolental fibroplasia.

Elongated ciliary processes were seen only in the patients examined after the retrolental membrane was completely developed.

SUMMARY

1. A survey for retrolental fibroplasia in 229 prematurely born children weighing less than 2,268 gm. at birth during a 5-year period was made in Cincinnati. No cases of retrolental fibroplasia were found in the group weighing above 1,814 gm. at birth. In 96 cases with birth weights of 1,814 gm. or less, 7 cases, or 7.3 percent, were found to have retrolental fibroplasia.

2. In this study the predominance of boys over girls among the infants affected with retrolental fibroplasia was statistically significant.

3. The following factors were considered in the etiology of retrolental fibroplasia: uterine bleeding during pregnancy, age and parity of the mother at delivery, occurrence of virus infections or chronic illness during pregnancy, cause of premature onset of labor, race, associated intracranial disease, administration of vitamin A in early postnatal life, and other factors in early postnatal management and course. The difference in the influence of these factors in affected and nonaffected prematures was not sufficient to be statistically significant and, therefore, the development of retrolental fibroplasia in this series cannot be attributed to them.

4. A description was given of three cases followed from birth until the development of retrolental fibroplasia.

AMPUTATION NEUROMA IN THE ORBIT*

FREDERICK C. BLODI, M.D.
New York

Although true neuromas are rather uncommon, amputation or traumatic neuromas not infrequently develop at the severed end of a nerve trunk. These neuromas are really only a proliferation of the nerve fibers and of the connective tissue. They represent a clubbed overgrowth of coiled trunks at the extremity of the severed nerve. The local thickening may simulate a neoplasm.

When it was first proved that these amputation neuromas were not true neuromas, they were believed to be connective-tissue tumors, in which the nerve fibers play a minor and completely passive role. This theory (Goldmann,[1] Finotti[2]) assumed that only the connective-tissue fibers proliferate, while the nerve fibers, at the most, only elongate.

We know now that the connective tissue of the nerve is the first to proliferate. This connective tissue of the endo-, peri-, and epineurium is usually the main part of these neuromas. But into this mass of mesodermal tissue the nerve fibers push their way. The axis cylinders elongate, branch, and ramify into the connective tissue. As they are prevented by the surrounding tissue from growing straight forward, they form twisted bundles of medullated or nonmedullated fibers. The newly formed axis cylinders may be provided with myelin sheaths, because the nuclei of this sheath multiply also. The amputation neuroma, therefore, is essentially a regenerative overgrowth, similar to changes in simple regeneration of nerve trunks. Some authors nevertheless attribute to it a certain neoplastic character.

Amputation neuromas are always present after a certain time in an amputated limb. They are painful only when they are constantly pressed upon or pulled by the surrounding tissue. Not only the severed nerve of an extremity can give rise to such a neuroma, but also the cut nerves of the trunk, such as the intercostal nerves (Gouverneur[3]) and the sympathetic nerve

(Leriche and Fontaine[4]).

There are few reports of amputation neuromas in the orbit. This is surprising, since the nerves of the orbit are often cut in various operations. They should especially be expected to occur after enucleation of the bulb and after exenteration of the orbit. There is no reason why the ciliary nerves should be an exception in this regard. Apparently these neuromas are seldom the cause of neuralgias in the orbit, as they are not exposed to any mechanical trauma. Also histologic examinations of the orbit are rarely made after enucleation or exenteration. The histologic examinations which have been reported (Bock,[5] Sattler[6]) were performed too early after the operation to allow the development of an amputation neuroma.

REVIEW OF LITERATURE

The first case of an intraorbital traumatic neuroma was described by Bietti,[7] in 1900. He discussed the regeneration of the nerves after opticociliary neurectomies. In one of his histologically examined cases he found a retrobulbar neuroma in the scar tissue. It was composed of connective tissue and thick, mostly myelinated, intertwined nerve trunks, forming a nodule.

Ten years later Loehlein[8] examined histologically a series of patients after opticociliary resection performed because of pain or as a prophylaxis against sympathetic ophthalmia. In 2 of his 6 cases he found an amputation neuroma behind the globe.

Adamantiadis[9] found an amputation neuroma in the orbit five years after an operation for a hydatid cyst. This neuroma caused considerable pain and was the size of a big hazelnut. The nerve fibers of the neuroma were mostly myelinated.

Recently Babel and Valerio[10] reported the first case of an amputation neuroma after an enucleation. It caused neuralgia four years after the operation. The tumor was the size of a small nut and was connected with the optic-nerve stump. All the fibers were nonmyelinated.

REPORT OF A CASE

A 3-year-old Negro boy, J. W., was admitted to the Institute of Ophthalmology on the service of Dr. A. B. Reese. For the previous 6 or 7 months, his grandmother had noted that the right eye looked peculiar. Except for the eye, examination showed the child to be healthy.

Ophthalmic findings. Right eye: The cornea was somewhat steamy. The anterior chamber was shallow and in its lower angle, in the region between the 5- and 6-o'clock positions, were some grayish white nodules. The iris was atrophic and several similar nodules were scattered over its anterior surface. Back of the lens was an orange reflex that occupied the whole pupillary area. The lens was clear, but pushed forward. The right globe was larger than the left one and showed a mild ciliary injection.

The left eye was normal; the fundus examined under general anesthesia showed no lesions.

X-ray films showed the typical mottled shadow of calcium density in the right orbit and none in the left. The optic canals were normal (Dr. R. L. Pfeiffer).

The diagnosis of retinoblastoma of the right eye was made and the globe with about 12 mm. of the optic nerve was enucleated. No implant was placed in the orbit.

The microscopic section revealed a retinoblastoma with total destruction of the retina. The choroid was invaded near the disc and near the ora serrata. Tumor cells were seen in the anterior chamber. The papilla of the optic nerve was densely infiltrated with tumor cells, which also grew through the lamina cribrosa. Additional islands of these cells were found farther behind the bulb in the optic nerve but the operative section was beyond the nerve invasion.

Postoperative course. Two months after the enucleation, there was noted in the apex of the right orbit a fullness which seemed to be somewhat more than could be accounted for by the muscle funnel. As the microscopic slides of the bulb did not show
Fig. 1 (Blodi). Microphotograph of a section through the amputation neuroma.

any extraocular extensions and the operative section was beyond the tumor invasion of the optic nerve, a recurrence did not seem probable.

The boy was not back for observation at the appointed time and only returned again to the clinic four months later. At this time a large, firm, sharply demarcated, freely movable mass was palpable in the middle of the right orbit. This mass measured about 30 to 35 mm. in diameter and was not painful. It lay in the muscle funnel and was not attached to the bone or surrounding structures. No preauricular or cervical lymph nodes were palpable. A recurrence of the retinoblastoma was diagnosed and the boy was again admitted to the hospital.

An exenteration of the right orbit with skin graft was performed. The postoperative course was uneventful. A part of the spec-

imen of the exenteration was prepared as a biopsy. It was the part of the tissue adjacent to the apex and it did not differ in consistency from the rest of the intraorbital contents.

The microscopic examination of the specimen revealed, to our great surprise, that this part was not a recurrence of the retinoblastoma, but an amputation neuroma (fig. 1). The nodule consisted of a mass of connective tissue and nerve fibers.

Centrally, the nerve fibers built up thinner trunks, which were densely interwoven with the connective-tissue fibers. These nerve trunks were twisted in all directions and crossed each other, so that on every slide they were cut transversely, longitudinally, and obliquely.

The connective tissue was dense and consisted of bundles of fibers, which were

similarly twisted. Toward the periphery of the nodule there was a preponderance of connective tissue which became denser and contained many capillaries and larger vessels. The nerve fibers were here arranged in larger trunks.

The nodule was poorly demarcated and had no capsule. It was surrounded by muscle tissue and by vessels. The muscle tissue was sharply demarcated from the nodule only in some places. In most parts the nerve fibers invaded the muscle tissue and spread among the muscle fibers, sometimes forming larger nerve trunks.

The major part of the intraorbital mass was prepared in the usual way. It showed a typical recurrence of a retinoblastoma. The tumor formed two nodules just beneath the conjunctiva. In the inferior periphery was a markedly thickened nerve running backward and becoming twisted. Apparently this was the place from which the biopsy was taken.

DISCUSSION

The formation of an amputation neuroma in the orbit is certainly not as rare as is generally supposed. Such a neuroma might arise after any operation during which larger nerves are severed. In the orbit, it is presumably generally small and rarely causes neuralgic pain. The reason it is not more often found is that it does not cause symptoms and histologic examinations of the orbit after an operation are rarely performed. Amputation neuroma can easily be overlooked, especially in those cases in which the enucleation was not performed because of a malignant tumor and there is no reason to examine the orbit postoperatively. It is also probably difficult to palpate such a small tumor when there is an implant in the orbit.

In our case, the amputation neuroma reached a considerable size within seven months after the enucleation, which is rather early. Amputation neuromas have been recorded developing between 16 months and 54 years after an operation (Jedwabnick[11]). It may be that the youth of the patient and the keloid tendency of his race were related to the rapid growth of the regenerative process. The early detection of the tumor was due to the fact that the patient was watched for a recurrence after an enucleation for retinoblastoma.

SUMMARY

The literature of amputation neuromas in the orbit is reviewed.

A case of amputation neuroma following an enucleation for retinoblastoma is reported.

HERNIATION OF THE ANTERIOR HYALOID MEMBRANE FOLLOWING UNCOMPLICATED INTRACAPSULAR CATARACT EXTRACTION*

ALGERNON B. REESE, M.D.
New York

Following an uncomplicated intracapsular cataract extraction the anterior hyaloid membrane may herniate toward the anterior chamber. If the membrane rests against the cornea or pushes the iris forward, there may arise various sequelae which will be discussed in this paper. It should be emphasized that the observations given are based on intracapsular extractions with no complications at the time of the operation and with normal restoration of the anterior chamber.

At the time of the first dressing or later there may be a central, poorly demarcated, disc-shaped opacity of the cornea. The opacity is located around the posterior surface and is accompanied by wrinkling of Descemet's membrane and some edema of the stroma.

If the anterior chamber is extremely shallow or absent, the opacity may be more extensive and not confined to only the central portion of the cornea. An examination of these cases under magnification and preferably with a slitlamp reveals the hyaloid membrane to be in apposition to the cornea. The contact of the hyaloid membrane with the cornea is a cause of so-called "striate keratitis" following intracapsular cataract extraction.

In these cases, particularly if there has been a round-pupil extraction, a strong miotic such as D.F.P. (di-isopropyl-fluorophosphate) should be used. If the herination is large, the miotic may not accomplish a complete regression of the hyaloid membrane but may leave a collar-button-shaped knuckle extending through the pupillary area. In such a case the patient should be in bed, lying on the back, and the pupil should be dilated with neosynephrin (10 percent) and reconstricted with the miotic. These measures usually accomplish a complete regression of the membrane and a clearing of the corneal opacity, edema, and wrinkling of Descemet's membrane, as well as a prompt whitening of the eye.

If the case proves intractable, the patient should be put to bed lying on the back, the pupil should be dilated with neosynephrin, and air or Ringer's solution should be injected into the anterior chamber followed by the instillation of D.F.P. The latter is indicated in the presence of a round pupil in order to lock the hyaloid membrane out of the anterior chamber.

This type of "striate keratitis" does not occur in cases of round-pupil extraction so long as the pupil is well constricted. In these cases the condition appears after the first dressing when the pupil has been dilated with atropine or some other mydriatic. In order to overcome the atropine promptly, we have employed D.F.P.

A pupil which has been small may dilate when the herniation of the membrane occurs, and a pupil dilated by a herniated membrane may not easily constrict.

When the membrane touches the cornea, it usually causes some irritation of the eye, giving the clinical appearance of a very mild iridocyclitis. Besides the slight redness of the eye and the corneal changes, lacrimation and, to a lesser extent, photophobia are noted. This combination is often interpreted as a mild postoperative iridocyclitis and is treated by mydriatics, especially atropine. The use of miotics and other measures when necessary causes the condition to clear promptly.

The apposition of the hyaloid membrane to the corneal surface seems to disturb the endothelium sufficiently to permit aqueous

to enter the cornea and thus produce edema of the stroma and overlying epithelium, particularly over the site where the hyaloid touches the cornea. Also, at the site of the apposition and in the region immediately adjacent to it, there is clouding and wrinkling of Descemet's membrane. If cornea guttata is present, so that the eye has the potentialities of an endothelial dystrophy, the apposition of the hyaloid causes more corneal changes than otherwise and may even lead to some permanent opacification.

Usually the herniation of the hyaloid membrane disappears spontaneously, and the membrane assumes a normal position in the pupillary area. When the membrane lies at the level of, or back of, the pupil, it usually shows a wrinkling. When it herniates into the anterior chamber, it usually presents a smooth, rather tense surface.

Kubik,[1] from an examination at the time of discharge of 526 cases of intracapsular extractions, found in 169 cases that the anterior hyaloid membrane projected flatly or in the form of a hemisphere. In the follow-up examinations he frequently could no longer see the protrusion of the hyaloid membrane. Vannas[2] could not give exact information regarding the frequency and rapidity of the recession of the herniation of the hyaloid membrane because he did not have a sufficient number of follow-up examinations.

In studying the anterior hyaloid membrane following intracapsular cataract extraction, there occurred an occasional instance in which a spontaneous rent in the membrane was noted months after the extraction. The membrane thinned out and, in the central portion where it was missing entirely, the vitreous protruded into the anterior chamber and over the surface of the iris.

Straight vitreous in the anterior chamber in these cases, or in those cases in which vitreous is lost at the time of operation, has not in my experience led to corneal changes.

From an examination of 32 eyes which had had intracapsular cataract extraction without loss of vitreous, Vannas found 10 cases with tears or holes in the anterior hyaloid membrane during a period of from 2 months to 4 years following the extraction. He felt that the hyaloid membrane more often showed a spontaneous rent in eyes in which the vitreous was diseased because a vitreous which became liquefied could manifest the same process by a weakening or even liquefaction of its hyaloid membrane. As most of the rents in the hyaloid membrane were located in the region of the pupillary margin, he speculated as to whether or not the action of the pupil could have had a slowly progressive traumatic effect.

Vannas found in 23 percent of the eyes with uncomplicated intracapsular cataract extraction that the anterior hyaloid membrane showed a concave surface and remained at the level of the pupil or even behind the pupillary border, and that in 61 percent of the eyes the height of the postoperative herniation of the anterior hyaloid membrane ranged from one fourth to one half the depth of the anterior chamber. In 9 percent of the eyes the anterior hyaloid membrane reached the posterior corneal surface. This author makes no mention, however, of corneal changes consequent to this herniation. His observations were made from the 7th to the 9th postoperative day.

Vannas also observed in his series of cases three instances in which during the period of observation with the slitlamp there was rapid alteration in the position of the anterior hyaloid membrane. For no apparent reason the membrane would alter its position from a state of herniation extending half the depth of the anterior chamber to a recession behind the pupillary border, forming a groove directed backward as deep as the hernia had been forward. He considered it possible that these fluctuations might be due to contraction and dilatation of the sphincter muscle of the iris, but that a more probable explanation was the state of contraction of the muscles composing the muscle funnel. He stated, however, that when these to-and-

fro movements of the vitreous are observed with the slitlamp, they seem to be entirely spontaneous.

The failure of the anterior chamber to restore, or the loss of the anterior chamber after it has been restored, following an intracapsular cataract extraction, may be due to advancement of the hyaloid membrane into the anterior chamber. Often a leaky wound is thought to be the cause of the absent chamber, but proof that this is not always the case is the fact that, if measures are taken to promote a retraction of the hyaloid membrane, the anterior chamber promptly restores, the corneal changes clear, and the symptoms subside.

An illustrative case is a round-pupil intracapsular extraction in which the anterior chamber was lost after it had been present for 12 postoperative days. Coincident with the loss of the chamber, there was increased redness of the eye, photophobia, lacrimation, and cloudiness of the cornea with wrinkling of Descemet's membrane. Examination with the slitlamp showed the hyaloid membrane against the posterior surface of the cornea. D.F.P. was instilled in the eye, the pupil contracted, the hyaloid membrane receded from the cornea, and, within five hours, the anterior chamber was restored, the cornea had cleared, and the symptoms had subsided.

After the cornea cleared, a choroidal detachment could be seen. The following day the pupil was dilated somewhat and the hyaloid membrane protruded but not so far as the cornea. D.F.P. was employed again and it has not been required since. The ability to influence a herniated hyaloid membrane by an intact iris is a distinct advantage of a round-pupil extraction. In cases of combined extraction the situation must be met by an injection of air into the anterior chamber.

There are rare instances in which recurrent herniations of the hyaloid membrane occur across the anterior chamber. These may take place any time, even up to years following the operation. When the membrane touches the posterior surface of the cornea, it causes a slight irritation of the eye with lacrimation, some photophobia, and even some discomfort or slight pain. The herniation may regress spontaneously, may recur, or may become permanent. These eyes usually show vitreous opacities and other indications of a very mild iridocyclitis which has apparently occurred as the result of the herniated membrane. Secondary glaucoma may ensue.

In one uncomplicated intracapsular cataract extraction there occurred even five years after the operation a slight congestion of the eye, vitreous opacities from a mild iridocyclitis, and reduction of the vision from 20/15 to 20/70. The only explanation I could find for this occurrence was that the anterior hyaloid membrane touched the cornea in the upper outer quadrant and produced corneal edema with epithelial stippling. The fact that there was some cornea guttata present may have aggravated matters. The hyaloid membrane became permanently adherent to the cornea over one area, and four years later the corneal edema and epithelial stippling had increased, some permanent scarring had ensued, and the intraocular pressure was elevated to 35 mm. of Hg (Schiøtz).

If the anterior hyaloid membrane does not retract spontaneously, or as the result of therapeutic measures, a permanent corneal opacity develops. This occurs because of the protracted period in which the membrane is in apposition to the cornea. Supposedly it may be facilitated by some trauma to the endothelium at the time of the operation. This trauma may be in the nature of corneal buckling when the lens is delivered, undue rubbing of the lens capsule across the posterior corneal surface at the time of the extraction or injuring of the endothelium with forceps or other instruments at the time of the operation. Thus, permanent scarring of the cornea ensues and the edema of the corneal stroma, as well as of the overlying epithelium, may persist indefinitely.

One case was observed in which the mem-

brane was in contact with the cornea for 3 months and caused corneal changes which cleared entirely when the membrane retracted. This eye was treated as a mild postoperative iridocyclitis and so atropine was employed. After the nature of the condition was appreciated, D.F.P. was used alternately with neosynephrin. The membrane retracted, the eye promptly whitened, and the cornea cleared.

When the membrane is permanently adherent to the corneal surface, the membrane may become thicker and denser adjacent to the site of the adhesion. This is thought to result from proliferation of the corneal endothelium over the surface of the adjacent hyaloid membrane.

If a permanent corneal opacity seems imminent in the pupillary area or adjacent to it, I think an attempt should be made to free the hyaloid membrane from the posterior surface of the cornea with a spatula. After this is done, air or Ringer's solution should be injected into the anterior chamber. If a round pupil is present, D.F.P. or some other strong miotic should be used with the patient in bed lying on the back. If the membrane cannot be freed from the cornea, I believe a deliberate rupture of the membrane would be beneficial.

Besides the usual type of iris prolapse* following cataract extraction, there is another type caused by the herniation of the anterior hyaloid membrane which pushes the iris ahead of it into the separated edges of the wound. The onset is insidious: it is not accompanied by pain and seldom by hyphemia. This may occur any time following the operation and tends not to be progressive. If operative measures are employed to correct it, an excision of the prolapsed

iris is accompanied by little or no escape of aqueous and, behind the iris, can be seen the anterior hyaloid membrane herniating toward the wound. Unless care is taken, this membrane may be ruptured. There is some doubt in my mind as to whether or not this type of iris prolapse requires a surgical repair.

If the anterior hyaloid membrane herniates toward the operative wound over the site of an iris coloboma, there results merely some degree of separation of the wound lips. Frequently there is also some cloudiness of the cornea adjacent to the wound. Calhoun[2] believes this is sometimes confused with early epithelization of the anterior chamber. After a round-pupil, uncomplicated, intracapsular extraction the iris will sometimes develop a coloboma at one site some weeks to months following the extraction. In such cases there has been no iris prolapse but merely a gradual development of a coloboma. At least in some instances this is due to a herniation of the anterior hyaloid membrane which pushes the iris peripherally, causing some degree of inversion or recession.

Secondary glaucoma may ensue because the anterior hyaloid membrane herniates sufficiently at the periphery to advance the iris and block the angle, or because the membrane itself blocks the angle over the site of a coloboma of the iris. When the anterior chamber fails to reëstablish or is lost following the extraction due to the forward protrusion of the hyaloid membrane, glaucoma may occur because anterior synechias are produced.

In these cases the rational treatment seems to be the freeing of the membrane from the corneal surface with a spatula, a cyclodialysis operation with injection of air into the chamber, and the use of a strong miotic when a round pupil is present. If the membrane cannot be freed from the cornea by the above measures, I am not sure that it would not be wise deliberately to rupture the anterior hyaloid membrane.

---

*I refer to the type which occurs characteristically from the 4th to the 6th postoperative day and is caused by the fact that the wound cannot withstand the restored intraocular pressure and ruptures with escape of aqueous which pushes the iris into the wound. This is accompanied by sudden pain and usually by a hyphemia. If the prolapsed iris is not repaired, the prolapse becomes more extensive. An excision of the iris is followed by a gush of aqueous.

The glaucoma that may ensue following a round-pupil extraction may be due to the fact that the membrane protrudes in a pyramidal fashion through the pupillary area and thus causes the ball-and-valve effect described by Chandler.[4] The observation in one case supports this mechanism: in this case the hyaloid membrane herniated through the pupillary area but not so far as the posterior surface of the cornea. Glaucoma was present and there was an iris bombé so that, particularly in the periphery, the iris extended forward almost to the posterior surface of the cornea.

In such a case a dilatation of the pupil, followed if possible by a constriction of the pupil, may suffice to relieve the glaucoma provided it has not been of too long standing.

The incidence of glaucoma is said to be less following a simple intracapsular extraction than following a combined intracapsular extraction.[5] Following a combined extraction, the hyaloid membrane herniates more frequently and farther into the anterior chamber than following a simple extraction. This seems to be due to the fact that the intact iris offers support to the membrane. This, therefore, may be a factor in the lower incidence of glaucoma following simple extraction.

In order to establish the representative character of the cases from which these observations have been made, I have analyzed 100 consecutive cataract extractions performed by me just prior to writing this paper. This series includes, therefore, the complicated as well as the uncomplicated cases.

There were 10 glaucomatous eyes, 7 of which had had 1 or more filtering operations; 4 radiation cataracts; 2 eyes with old uveitis; 2 eyes with neurodermatogenous cataract; 1 cataract complicating retinitis pigmentosa; 1 cataract associated with detachment of the retina; and 1 cataract complicating malignant myopia. The complicated cataracts, therefore, were 21 percent. Ninety-two percent of the lenses were delivered in

capsule. This includes 2 cases in which the capsule ruptured as the lens came through the wound. No capsule and no soft lens matter remained in the eye, and this was confirmed by the postoperative course. A third case in which the capsule ruptured as the lens came through the wound was not considered a delivery in capsule because some capsule remained in the eye and necessitated reëntering the anterior chamber to remove it.

Vitreous was lost at 4 operations, or 4 percent. Two of these were in the complicated group, one being a case of malignant myopia of over 20 diopters in which watery vitreous appeared at the time of the keratome section.

DISCUSSION

The anterior hyaloid membrane normally extends from the base of the vitreous around the posterior chamber and makes contact with the lens at a site termed the "ligamentum hyaloidea capsularis." This membrane, which is much thicker than the posterior membrane, is a definite, rather dense, thick structure composed of a condensation of the vitreous elements. There is some histologic evidence to indicate that the membrane has a somewhat laminated structure. Outstanding characteristics of the membrane are its distensible and elastic properties.

At the time of a cataract extraction the membrane may bulge through the operative section. As the result of proper maneuvers, this herniation may retract and assume its normal or near-normal position. Following a contusion to the eye, the zonules may be ruptured and the anterior hyaloid membrane may herniate into the anterior chamber, the resultant appearance being one of a well-demarcated, globular mass which may recede or remain.

The anterior hyaloid membrane is normally in contact with the lens at the site of the ligamentum hyaloidea capsularis. It must be assumed that ordinarily this union is

merely one of apposition. Otherwise, if there were a firm ligamentous union, a rent would be torn in the anterior hyaloid membrane when an intracapsular extraction was done. There must, however, be variations in the degree of union between the membrane and the lens capsule. Even though in the majority of instances it may be merely one of apposition, there must be instances when an actual union of the two exists.

Thus, in these cases, when an intracapsular extraction is performed, the removal of the lens pulls away at least some of the lamellae of the anterior hyaloid membrane. If, then, this should occur, it may weaken the anterior hyaloid membrane and, therefore, predispose it to ectasia even under the normal vitreous pressure.

Likewise, there must be rarer instances in which a firm adhesion exists between the two. In these cases the removal of the lens causes an actual tear in the hyaloid, and this may account for the times when the delivery of the lens is followed by normal-appearing vitreous not under pressure.

For our discussion here, however, we are interested in the possibility that such a lens extraction may reduce the lamination of the hyaloid and thus weaken it. Clinically, evidence in support of this occurrence is the fact that under the slitlamp the thickness of the anterior hyaloid membrane following intracapsular extraction seems to vary considerably. In some instances it is even difficult to see. In others it is absent over an area where the vitreous is seen protruding into the anterior chamber through a rent or hole in the membrane.

Vannas found upon examination of 100 recent cases of intracapsular cataract extraction without loss of vitreous that there were 8 instances in which he could detect with the slitlamp a tear in the anterior hyaloid membrane.

It appears, therefore, that the anterior hyaloid membrane may be torn at the time of operation without loss of vitreous provided there is no vitreous pressure present. This tear or hole must be caused by an adhesion at the site of the ligamentum hyaloidea capsularis.

There are rare examples, particularly in complicated cataracts, perhaps as a result of inflammatory adhesion, in which there is a very firm adhesion between the posterior lens capsule and the anterior face of the hyaloid membrane. When such a union is firm, the surgeon appreciates it at the time of the intracapsular extraction because, as the lens comes forward, there is a feeling of an advancement of the entire vitreous body with it. In such an instance it may be necessary to peel or separate the hyaloid membrane from the lens capsule in order to remove the lens.

In the herniation of the anterior hyaloid membrane following an intracapsular cataract extraction, I believe an important factor is the change in the vitreous volume. It is necessary to assume such an occurrence to explain the transitory and even recurrent nature of the herniation. Lindner[5] claims that, following every cataract extraction as well as in all fistulizing eyes, there is a posterior detachment of the vitreous due to shrinkage.

The shrinkage of the vitreous may be due to aqueous replacement which in the aphakic eye is greater than in the phakic eye. Later, if the vitreous takes on fluid and regains its former volume, or even a portion of it, the anterior hyaloid membrane may protrude into the anterior chamber if the posterior vitreous detachment still persists.

It seems to me that a decrease in the lamination of the anterior hyaloid membrane (thus a thinning) as well as an increase in the vitreous volume must be assumed to explain the various manifestations of the herniation. The increase in the vitreous volume might explain the usual cases in which the hyaloid membrane protrudes straight through the pupillary area, but alone it would not explain the other cases in which the hyaloid membrane protrudes at a site away from the pupillary area. In these cases

it appears that a localized weakening of the membrane must also be assumed.

An instructive case was one in which the capsule broke after the lens had been dislocated over the lower one third. Postoperatively the patient developed a herniation of the anterior hyaloid membrane over the lower one third at the site where there was no remaining capsule. The membrane touched the cornea and produced a corneal opacity and edema at this site. The explanation must be that the anterior hyaloid membrane bulged at the site of least resistance when the vitreous volume was regained.

There are many who believe that, following a cataract extraction or a fistulizing operation, a choroidal detachment occurs secondary to a shrinking of the vitreous. If such is the case, the incidence of choroidal detachment should be less in extracapsular extraction than in intracapsular extraction. This is assumed because, when the vitreous regains its volume, the presence of the capsulozonular barrier prevents it from protruding into the anterior chamber. Therefore, it must expand posteriorly and decrease the posterior vitreous detachment, and thus the choroidal detachment. In other words, the anterior hyaloid membrane protrudes into the anterior chamber because this is the course of least resistance when the vitreous volume is replaced.

Von Sallmann[7] made some interesting observations on the behavior of the anterior hyaloid membrane following uncomplicated intracapsular cataract extraction. He noted that at the time when a detachment of the choroid is fully developed there is a definite herniation of the hyaloid membrane into the anterior chamber. When the choroidal detachment begins to subside, the bulging of the anterior hyaloid membrane recedes. This recession of the choroidal detachment and the recession of the herniated anterior hyaloid membrane go hand in hand until finally there is an actual depression or concavity of the hyaloid membrane behind the plane of the iris. This phenomenon was not noted in all cases of detachment of the choroid but only in those which regressed rapidly.

After the choroid becomes completely reattached, the recession of the anterior hyaloid membrane disappears, and the membrane assumes a normal position. The changes in the position of the anterior hyaloid membrane are coincident with those of the choroidal detachment and take place over a short period, the longest being several days.

Von Sallmann explains the recession of the previously protruding hyaloid membrane coincident with the reattachment of the choroid as follows: When the reattachment of an extensive detachment of the choroid proceeds rapidly, the regulation of the fluid absorption by the vitreous is not sufficiently rapid to prevent a temporary reduction in the vitreous volume. In this process the vitreous, which is adherent to the internal ocular structures, follows the receding choroidal surface, and this is manifested on the face of the vitreous by a retraction.

Lindner[6] integrates this phenomenon with his conception of a detachment of the choroid produced by a shrunken vitreous body in the following manner: The action of the vitreous on the choroid is generally horizontal, thus giving rise to the well-known manifestation of a choroidal detachment nasally and temporally. When the filtration of the operated eye, and therefore the abnormal production of aqueous, ceases, the pressure within the eye returns to normal. The vitreous thus tends to regain its normal volume. At this stage, however, any choroidal detachment present begins to recede, and the absorption of the subchoroidal transudate is apparently more rapid than the increase in vitreous volume, so that the anterior hyaloid membrane temporarily is retracted.

Further interesting observations were made by von Sallmann:[7] In a patient with secondary glaucoma following an uncomplicated intracapsular extraction, a cyclodialysis operation was performed and, at the time when the intraocular pressure was normalized as a result of the glaucoma op-

eration, he noted a herniation of the anterior hyaloid membrane into the anterior chamber.

Moderate pressure upon the eye through the upper lid caused the herniation to project farther forward, and fine wrinkles in the surface of the membrane disappeared. Following massage of the eye for one minute, the hyaloid herniation bulged farther and the membrane appeared more tense. Five minutes later the hyaloid membrane had receded behind the plane of the iris and showed wrinkling. Twenty-five minutes later the membrane had receded still farther behind the plane of the iris. One hour later the hyaloid membrane again herniated to the same degree to which it had before the massage was done.

The drainage of aqueous occasioned by the cyclodialysis operation ceased to function later, and the intraocular pressure rose to 50 mm. Hg (Schiøtz). The anterior hyaloid membrane lay behind the plane of the pupil. Pressure upon the globe through the upper lid caused the membrane to bulge markedly into the anterior chamber, but upon release of the pressure the hernia returned slowly to the level of the pupil. After massage of one minute the membrane still remained at the level of the pupil.

These observations indicated that, during the time in which the cyclodialysis operation was effective, the pressure upon the eye, as well as the massage, caused a definite increase in the extent of the already bulging hyaloid membrane. When the cyclodialysis operation became ineffective, the pressure and the massage on the eye produced no appreciable bulging of the membrane into the anterior chamber. Immediately following the massage, when the filtering operation was functioning, there was a rapid recession of the membrane. As a result of the communication between the anterior chamber and the suprachoroidal space, pressure and massage upon the eye forced the aqueous into the suprachoroidal space. As the aqueous from the anterior chamber decreased, the vitreous hernia could bulge farther into the anterior chamber. When the cyclodialysis was draining, the pressure and massage on the eye caused fluid to be forced out of the vitreous, and from 30 to 45 minutes was required for the vitreous volume to be replaced.

SUMMARY

The contact of the anterior hyaloid membrane with the posterior corneal surface following uncomplicated intracapsular cataract extraction causes symptoms and signs which disappear if therapeutic measures are successful in causing the herniated membrane to recede from the corneal surface.

DISCUSSION

DR. EDWIN B. DUNPHY (Boston): Dr. Reese's thorough presentation of this interesting subject has given us much food for thought. It emphasizes the harmful potentialities of the vitreous when this substance leaves its normal confines and spreads forward to new boundaries. Although many ophthalmologists are aware that vitreous in contact with the corneal endothelium for any length of time may give rise to edema of the

cornea, its occurrence in my experience has been extremely rare, considering the prevalence of vitreous herniation.

Dr. Reese apparently feels that this contact is the chief cause of the so-called striate keratitis seen postoperatively, although he mentions that it may be facilitated by damage to the corneal endothelium. It has always been my impression that damage to the endothelium at the time of operation is the *main* factor, since striate keratitis occurs just as frequently after extracapsular extraction where there is no possibility of vitreous touching the cornea.

It is my endeavor in intracapsular cataract surgery to deliver the lens by the Verhoeff sliding technique, the capsule being grasped at or near the upper equator with smooth forceps and pressure being made at the limbus below. A small iridectomy including the sphincter is performed before the delivery. The wound is closed by two Verhoeff corneoscleral tract sutures. By this method of extraction I feel that minimal damage to the cornea occurs.

The anterior chamber is reformed at the first dressing (24 hours). It is extremely rare to see any gross striate keratitis either then or subsequently, although slitlamp examination is not done until the 6th or 7th postoperative day, and it is possible, of course, that it might have been present earlier to a slight degree. At this examination vitreous is invariably found herniating through the pupillary space, sometimes practically in contact with the cornea, although not attached thereto. Wrinkling of Descemet's membrane is present in all cases, even when the hyaloid is nowhere near the cornea. In a few cases in which the reformation of the anterior chamber is delayed for a few days, I have not seen the saucer-shaped corneal opacity which Dr. Reese describes, although there is usually a lot of wrinkling of Descemet's membrane due to the hypotony.

I was interested in the quotation of Vannas's statistics to the effect that, in 23 percent of eyes with uncomplicated intracapsular

extractions, the anterior hyaloid membrane showed a concave surface and remained at the level of the pupil, or even behind the pupillary border. In my uncomplicated cases I would estimate that practically 100 percent show some protrusion of the hyaloid in front of the pupillary border, in most instances extending halfway across the anterior chamber, and in some of them the vitreous is almost in contact with the cornea. Even when observed several years postoperatively this is true, although there tends to be a gradual retraction of the hyaloid. It is quite probable that, if I did round-pupil extractions, the incidence of extensive herniation would be less.

There is no doubt, of course, that corneal edema and opacification can be caused by adherence of the vitreous to the endothelium, particularly if the latter is damaged. Dr. Cogan of the Howe Laboratory, who has been making a special study of corneal edema, considers vitreous adherence to be an important contributory cause. Unlike Dr. Reese, he feels that the presence of the intact hyaloid is not essential; in other words, the edema may result from free vitreous in contact with the cornea following vitreous loss at operation. The condition of the endothelium is the determining factor. If it is in bad shape, either because of trauma at the time of operation or because of inherent degeneration, then the vitreous may stick to it with all the dire effects that Dr. Reese describes.

The injection of air to free the adhesion of vitreous to cornea has been attempted recently in one case at the Massachusetts Eye and Ear Infirmary. The patient, a man aged 68 years, had had intracapsular cataract extractions in each eye three years previously. Vitreous had been lost in one eye but not in the other. Both eyes showed vitreous herniating through the pupils and attached to the upper part of the endothelium at the line of incision. Edema of each cornea was present over the point of vitreous adherence. A shelving incision was made in the cornea

below just inside the limbus with a cataract knife. A good blast of air injected through this incision by a small needle and glass syringe succeeded in freeing the vitreous from the endothelium with subsequent clearing of the cornea to a large extent. The same process was successfully repeated in the other eye.

I am not familiar with the special type of iris prolapse caused by the vitreous pushing the iris into the edges of the wound as described by Dr. Reese, but see no reason why it should not occur, particularly in round-pupil extractions.

In similar fashion secondary glaucoma might be caused by vitreous pushing the iris root against the angle.

I have seen several cases in which the glaucoma was due to vitreous blocking the pupil according to the mechanism recently described by Chandler. In these cases there was a tendency to iris bombé, and a transfixion of the iris in the periphery relieved the situation by reëstablishing communication of aqueous between the posterior and anterior chambers.

The technique advocated by Dr. Reese of dilating the pupil, placing the patient on his back, and then constricting the pupil with a strong miotic might well be helpful in this type of case, particularly after round-pupil extractions.

The creation of a coloboma by the herniating vitreous pushing the iris peripherally has been observed by me on several occasions. A round pupil is not necessary for its production. Apparently in these cases the hyaloid ruptures, or thins out, not in the center of the pupillary zone, but to one side, so that the vitreous bulges through just behind the pupillary margin, shoving it toward the periphery. I have recently had such a case. During delivery of the lens some difficulty had been encountered in getting it to dislocate. Suddenly it gave way nasally, popping up into the wound. Extraction in capsule was completed without loss of vitreous. The next day

the chamber was reformed and the operative result appeared to be perfect. On the third postoperative day I noticed a coloboma of the iris developing nasally. This increased slowly during the next three days. Slitlamp examination on the sixth postoperative day showed the picture just as Dr. Reese describes—the vitreous was bulging nasally, the adjacent pupillary border being displaced toward the periphery.

The author's supposition of a partial adhesion between the anterior hyaloid and the posterior surface of the lens to explain the weakening and bulging of the hyaloid following extraction is a reasonable one, and answers the question why this bulging sometimes takes place on one side and not in the center of the pupillary space.

The other factor he mentioned concerning the shrinkage of vitreous with choroidal detachment, and the correlation of changes in the position of the anterior hyaloid with the changes in vitreous volume, is an interesting one, and helps us understand the mechanism of vitreous herniation.

I have learned a lot from this paper, and am indebted to Dr. Reese for clearing up in my mind some things I never understood about herniation of the vitreous.

DR. F. H. VERHOEFF (Boston): I am much interested in this paper of Dr. Reese's and think it is a very important communication. I agree with most of the things he brought out, but it would take me about an hour to discuss all the aspects of the subject so I shall confine myself to just one, the permanent serious opacification of the cornea which results from adhesion of the vitreous to the back of the cornea. Some of us at the Massachusetts Eye and Ear Infirmary have known about this for at least 15 years. I would like to think I was the first one to get the idea, but my impression is that Dr. Gundersen is entitled to most of the credit.

For a good many years I had in mind a method of combating this opacification of the cornea but it was not until 1944 that I used

the method. I began to write up the case, but when I looked up the literature I could not find that anyone else knew anything about the condition, so it seemed foolish to report an operation for combating a danger that was almost unknown. I was, therefore, very much pleased to learn that Dr. Reese had established the fact that it was a serious condition with which I was dealing.

In March, 1944, I operated on the right eye of the patient, doing an intracapsular cataract extraction without loss of vitreous. She had 20/20 vision in this eye and wished me to operate upon the other eye, which I did three months later. She acted very well in the first operation, but in the second she was not a good patient, or at least that is to what I attribute the fact that I lost vitreous. The loss of vitreous was so slight that the pupil was not drawn up, but vitreous became adherent to the back of the cornea over a large area, about two thirds of the cornea. She began to get definite corneal opacification which, according to my experience, has been permanent and serious.

She was so well pleased with the right eye that she had the utmost confidence in me, very fortunately, otherwise I could not have done what I did for the left eye. She had edema of the cornea and opacification, so I decided that eye would be ruined if I did not do something. I made a keratome incision, let out all the vitreous that would come, and then I even put an irrigating tip in the anterior chamber, but irrigation did not bring out much more vitreous. I used only one suture this time. The wound healed very well and the anterior chamber was free of vitreous. The cornea cleared up except for a slight opacity high up, which is there today. But, as usually happens after a primary large loss of vitreous, the pupil became drawn up so high that one could hardly see it, and the eye remained irritable for months. The eye therefore had very little vision at that time. The patient stuck by me all this time in spite of photophobia and discomfort.

At the end of nine months, when the eye had become white and quiet, I did a small iridotomy with a Ziegler knife and obtained 20/30 vision, which she still has.

I suspect that a slight loss of vitreous is more likely to produce the condition than a large loss. After a large loss I think most often the vitreous goes back to the level of the pupil. I do not think it is necessary for the hyaloid to be in front of the vitreous. It is the contact of the vitreous with the cornea that produces the opacification. Dr. Cogan thought possibly opacification would be more likely to occur if there was cornea guttata. Cornea guttata was present in both eyes of my patient. I have not had many of these cases myself, but I have seen the condition a number of times in eyes operated upon by other surgeons.

I recall one case especially in which I wish I had done this operation of vitreous removal. The patient had been operated upon in Hartford by one of the members of this society and had opacification of the cornea. I thought the operation must have been badly done, and I would do a better one, so I operated on the other eye and had exactly the same thing happen. The man was a very "bad actor"; I lost vitreous and I imagine my colleague in Hartford did also. Both eyes had such opacification of the corneas that the patient could only count fingers. I feel sure that if I had removed the vitreous from the anterior chamber before serious opacification of the cornea had occurred, this patient would have obtained good vision.

DR. WILLIAM P. BEETHAM (Boston): I would like to say a few words in behalf of the injection of air into the anterior chamber at the time of cataract extraction. Some of us in Boston have been somewhat disappointed with the injection of air into the anterior chamber in some of the late cases of this complication which we are talking about. By late cases I mean those with serious corneal damage in which adherence of the vitreous to the posterior surface of the

cornea has occurred at a rather late date following cataract extraction. The vitreous, either free or with the hyaloid intact, can be pushed back from the posterior surface of the cornea, but usually by the time this is done the corneal changes are severe and irreversible, and the situation proceeds, namely, edema, bullous keratitis, and corneal opacities.

Since vitreous prolapse can occur postoperatively from hours to days following operation, it does not seem reasonable that anyone can predict which eyes will be affected, and when. The chances are that, when these people appear for treatment, they will have seriously damaged corneas or irreversible changes. In contradistinction to that group for which little can be done are the early cases, for which I think considerable can be done, namely, prevention, and by prevention I mean preventing the occurrence of the adherence of the vitreous to the posterior surface of the cornea by doing something at the time of operation.

I think at this point we ought to thank Dr. Reese for admirably describing this condition and bringing it to our attention. For 6 or 7 years I have made it my routine procedure to inject not a bubble of air but if possible to fill the anterior chamber with air at the time the cataract is removed through my iridodialysis opening after two Verhoeff stitches have been tied.

Last week I inspected the records of 300 operations done during the last three years, and I found one case which fufilled Dr. Reese's description. That patient was one in whom striate opacity was noted at the first postoperative dressing. It has persisted for two years with a maintained acuity of 6/12; vitreous is still adherent to the posterior surface of the cornea. In my description of the record of that operation, believe it or not, I make the statement "no air was injected into the anterior chamber." Why, I do not know, but I operated on the other eye of that patient two years before that operation and air was injected into that anterior chamber,

and she had a good result, so it is interesting to me that the eye in which air was presumably injected did not develop this complication.

My point is merely this, that for some time I have believed that the injection of air into the anterior chamber immediately following cataract extraction is an important addition to the modern cataract operation, and I think Dr. Reese's paper has made me feel more decisive about it.

DR. CHARLES A. PERERA (New York): I wish to agree with Dr. Dunphy in his remarks in regard to the cause of striate opacification. I think Dr. Reese's thesis on herniation of the anterior hyaloid membrane is only one of the causes, and perhaps not the main cause in most cases. I wish to report an example of this condition following a cataract operation with round pupil and a peripheral iridectomy. This was done on an 81-year-old man; the postoperative course was uneventful, and air was injected into the anterior chamber at the close of the operation as Dr. Beetham has done for years. The night after the operation the patient got out of bed and wandered about until he was finally put back to bed.

At the first postoperative dressing the anterior chamber was filled with blood which extended under the conjunctival flap. When the blood was sufficiently absorbed a small iris prolapse was seen temporally; the cornea in this quadrant showed striate opacification and the blood-filled vitreous pressed against the cornea in this quadrant. After consultation with Dr. Reese, and in accordance with his suggestion that air injection might be worth while, I performed this procedure as Dr. Dunphy described it. The vitreous was pushed back from the cornea, the corneal opacification rapidly disappeared, and the vitreous is now clearing.

DR. RALPH O. RYCHENER (Memphis): I enjoyed Dr. Reese's paper and its very timely explanation of a number of things which I have been puzzled about, and I want to add a little confusion to it. With regard

to air injection immediately following intracapsular cataract extraction for uncomplicated cataract, in the past two years I did that routinely, employing the method suggested by Dr. MacMillan in which I put in a lot of air, enough to depress the iris, and it was during that period I ran into all the complications of herniation of the vitreous against the endothelium which I have encountered in my limited practice. So after reviewing my operations I decided perhaps the air was responsible for the opacification of the cornea and have now stopped air injection. I would like to ask Dr. Reese, when he dilates with neosynephrin and employs strong miotics, how long does he employ the miotic, and what happens after he stops it?

DR. ALFRED COWAN (Philadelphia): I have been interested in this subject for many years, and particularly in the acceptance of the term "anterior hyaloid membrane." In 1931, I presented a paper before this society describing the anterior hyaloid membrane; in 1932, Dr. Fry and I gave what we thought was conclusive evidence that there is such a thing as an anterior hyaloid membrane and, in 1939, before this society again, Robb McDonald and I presented a report of a series of cases of postoperative aphakics.

In this series was a group in which the lens and its capsule were supposed to have been extracted—intracapsular extractions. In nearly every one of these cases, immediately after the operation, the anterior hyaloid protruded far into the anterior chamber, and in many instances it was in contact with the posterior surface of the cornea over quite a large area. I should say in most of the cases we examined protrusion of the hyaloid into the anterior chamber persisted until the 5th or 6th day.

After that—now I am describing those in which the operation was successful, in that the hyaloid membrane was intact—after that, the hyaloid retracted gradually and, in the majority of instances, later on it would lie in the plane behind the iris without anything having been done for it. It seems to me after all this time (and I have studied a great many of these conditions) that it is not a matter of pressure from behind that causes the hyaloid to protrude but rather it is due to a lack of pressure or support in front.

As far as striate keratitis is concerned, I think it is possible that herniation of the hyaloid is a factor; but I do not think it is an important factor, because in almost every case after you open the globe you will find some indication of folds in Descemet's membrane or in the posterior portion of the cornea. I should like to show a slide which contains illustrations from an article by me and of one by McDonald and me. The first drawing illustrates a case that can be considered a narrow slitlamp appearance of the hyaloid membrane which is concave from before backward and lies behind the plane of the iris. This is what is considered a successful extraction of a lens with its capsule after 6 or 7 days. There is a drawing of a case in which a permanent herniation resulted; it is hemispheric. This is not a rare result. Another represents an instance in which the hyaloid lies in horizontal folds. One drawing illustrates a case in which blood in the vitreous is contained in the hyaloid which protrudes into the anterior chamber over the lower border of the pupil. After the blood became absorbed, the hyaloid membrane contracted behind the plane of the iris. Another is an illustration of an instance in which the hyaloid became incarcerated in the wound. It seems to me that such cases are not due to pressure from the force behind but that the hyaloid is drawn into the wound as the knife is withdrawn.

DR. ARTHUR J. BEDELL (Albany, New York): I wish to show one slide which has some historical interest because it was exhibited almost a quarter of a century ago. You can see the vitreous prolapse in each drawing. Dr. Reese told me he had not seen the article which was presented before the English-speaking Congress in 1925. It is for that reason I present it to those who may be unaware of this early work.

DR. ALGERNON B. REESE (closing): Dr. Dunphy mentioned the fact that he and also Dr. Cogan feel that the condition of the endothelium is an important factor in the corneal changes. I agree with them. I mention in the paper that if cornea guttata is present the corneal changes are more severe.

Dr. Dunphy also mentions the fact that herniation of the hyaloid may produce a coloboma of the iris. This point is also discussed in the paper.

A feature of Dr. Dunphy's and Dr. Verhoeff's discussion with which I am not entirely in accord is that dealing with the ill effects of straight vitreous on the cornea. I am not sure that vitreous alone produces corneal changes. I think the changes I have observed have occurred as the result of the hyaloid membrane. This membrane has a definite structure and it is the effect of this against the cornea which promotes symptoms and signs.

I was glad to hear Dr. Verhoeff state that he felt a deliberate rupture of the hyaloid membrane is indicated sometimes. I have thought that this might be beneficial sometimes in cases with permanent adhesion of the membrane to the cornea, and in cases with secondary glaucoma.

Dr. Beetham mentions the value of air injections. I think they have value not only in pushing the iris back but in pushing the hyaloid back. I recall the case which Dr. Perera quoted, and I feel, as he did, that the injection of air was beneficial.

Dr. Rychener asks how long miotics are used. I think a period of about 2 to 3 days is adequate.

I know of Dr. Cowan's work. I referred to the hyaloid as a membrane which is in agreement with his ideas. I thank Dr. Bedell for calling my attention to the article which he wrote in 1925 pertinent to this subject.

OPHTHALMIC MINIATURE

Blumen

(Dem Augenarzt von seinen Kranken.)

Sie kommen aus dem Schoss der Nacht:
Doch waren unten sie geblieben,
Wenn nicht das Licht mit seiner Macht
Hinauf ins Leben sie getrieben.

Holdselig aus der Erde bricht's,
Und blüht nun über allen Schranken;
Du bist der Freund des holden Lichtes:
Lass dir des Lichtes Kinder danken!

THE ROLE OF CILIARY AND SUPERIOR CERVICAL GANGLIA IN OCULAR TENSION*

Ernst Schmerl,[†] M.D., and Bernhard Steinberg, M.D.
Toledo, Ohio

This study is a part of a general investigation of the factors which affect intraocular pressure. In a previous report it was indicated that the diencephalon contained a center or centers which exercised a regulatory control of intraocular pressure.[1] In a subsequent paper[2] it was shown that the central control of tension involved the pituitary body. The presence of two active principles, probably hormonal in nature, was found in the region of the posterior lobe of the pituitary. One of these principles increases and the other decreases the tension. In a normal state they are in an equilibrium. Apparently, these active principles are secreted into the spinal fluid and they act upon the diencephalic center or centers.

It was postulated that stimuli which are induced in the diencephalon are transmitted through the medium of the autonomic nerve fibers to the eyeball. These stimuli dilate or constrict capillaries depending upon the predominance of either of the two principles. There is ample clinical and experimental proof that capillary action represents one mechanism which determines ocular tension.[3]

The present study concerns itself with the role of the ciliary and superior cervical ganglia in ocular tension and the postulated mechanism which is outlined in this paper.

Saitoh[4] extirpated the ciliary ganglion and found an immediate decrease of intraocular pressure which returned to normal in an hour. The tension was low again the second day and returned to normal within two weeks. Peschel[5] described a procedure for removal of the ciliary ganglion and noted a decrease in tension. Givner,[6] among others, pointed out the occurrence of accessory cili-

ary ganglia. Linksz[7] observed the effect of the sympathetic pathways on ocular tension.

EXPERIMENTAL PROCEDURES

Rabbits were used as experimental animals. The ciliary ganglion was reached by a bipolar electrode which was insulated except for the tip. The electrode could either stimulate or cauterize. The tip of the electrode was introduced through an incision in the anterior lower part of the eyelid after removal of the tear and Harder glands. The electrode was guided by the trigeminal nerve to the region of the ciliary ganglion. Contact with the ganglion was recognized by contraction of the pupil and a rise in the ocular tension after stimulation. Stimulation was followed by cauterization. The method was not universally successful. Only those animals were used in the experiments in which the pupils were dilated, the pupillary reflex was absent, the wink reflex was retained, the corneal sensation remained intact, and the fundi were normal.

The left ciliary and the superior cervical sympathetic ganglia were stimulated and cauterized in 10 rabbits. The ocular tension was determined prior to the action upon the ganglia and immediately after stimulation and up to 21 days following cauterization. In 4 animals with cauterized ciliary ganglion, ocular tension was determined after administration of distilled water for 60 to 90 minutes.

In 7 rabbits, following either cauterization of the ciliary ganglion or excision of the superior cervical, spinal fluid, in volumes of 0.5 to 0.8 cc., of animals exposed to dark or to light was injected. The tension was determined for 60 to 90 minutes following the injection. Normal animals were injected with identical spinal fluid and were used as controls. As in our former studies, changes

in tension of 3 or more mm. Hg (Schiøtz) were considered significant.

RESULTS

Stimulation of the ciliary ganglion in 5 animals resulted in an immediate increase of

TABLE 1

EFFECT OF FARADIC STIMULATION OF THE CILIARY OR SUPERIOR CERVICAL GANGLION UPON INTRAOCULAR PRESSURE

8		23	16

intraocular pressure of from 8 to 17 mm. Hg (table 1). Other changes consisted in pupillary contraction, marked hyperemia of the iris, flattening of the anterior chamber, and haziness of the iris. These changes are indicative of stimulation of the parasympathetic fibers of the oculomotor nerve with a resultant capillary dilation and increased permeability.

Cauterization of the ciliary ganglion in 6 animals resulted in a decrease of intraocular pressure of from 8 to 13 mm. Hg (table 2).

The readings were taken at intervals of from 1 to 28 days. Generally, the ocular tension showed a tendency to slight recovery after several days. Other changes which were observed consisted of pupillary dilatation and loss of light reflex.

Cauterization of the ciliary ganglion followed a month later by ingestion of 40 cc. of distilled water per kilo body weight resulted in little or no change. Under normal conditions, with an intact ciliary ganglion, the tension rises (table 2).

Cauterization of the ciliary ganglion followed 5 to 7 months later by intravenous injection of spinal fluid from animals kept in the dark showed a reduction of ocular tension equal to that found in normal animals (table 3). The reduction occurred within 15 to 20 minutes and persisted for the subsequent 30 to 60 minutes. Injection of spinal fluid from animals exposed to light showed no change. On the other hand, the intraocular pressure was elevated in the control animals (table 3).

These changes indicate that removal of the parasympathetic pathway results in a failure to transmit those stimuli which cause an increase in tension. At the same time, there is indication that there is no interference with the active principle which causes a decrease in tension.

Stimulation of the superior cervical ganglion resulted in a lowering of the intraocular

rabbits exposed to darkness showed no significant change in tension (table 4). These changes indicate that removal of the sympathetic pathway results in a failure to transmit those stimuli which cause a decrease in tension. At the same time there is indication that there is no interference with the active principle which causes an increase in tension.

SUMMARY

Under the conditions and on the basis of these experiments, it may be postulated that stimuli travel from the diencephalon by way of the ciliary ganglion, which is essentially of parasympathetic nature, and produce vascular dilatation with a consequent increase in ocular tension.

On the other hand, those stimuli from the diencephalon which travel by way of the superior cervical ganglion, a sympathetic conveyer, contract capillaries and produce a lowering of intraocular pressure. Light and darkness incite the production of active principles in the pituitary. These principles act upon the diencephalon and initiate nervous stimuli which are transmitted to the periphery along the autonomic pathways.

OPHTHALMIC MINIATURE

Celsus contains a summary of all that was known in his time. Although he was ignorant of the seat of cataract, he has described the operation of couching excellently and concisely, not omitting the important subjects of previous preparation and after treatment, for which his directions are judicious.

Sir William Lawrence, *A Treatise on the Diseases of the Eye,* 1833.

THE EPIDEMIOLOGY OF EPIDEMIC KERATOCONJUNCTIVITIS*

PHILLIPS THYGESON, M.D.

San Jose, California

The recurrence of epidemic keratoconjunctivitis in California in epidemic form in 1947 and 1948 indicates that this disease, which first became widespread in the United States in 1941, is probably to be a permanent problem. Although it failed to have the expected military significance during the war years, it did become an industrial problem and would seem to be potentially capable of causing major disturbances in the future.

In view of the office transmissions which occurred in both the 1941-1942 and the 1947-1948 epidemics, and in the course of which many ophthalmologists became infected, it would seem pertinent at this time to reëxamine the epidemiology of this important disease. The present clinical study is based on my personal observations, on the observations of a number of colleagues, and on epidemiologic studies previously recorded in the literature.

CLINICAL CHARACTERISTICS

The clinical characteristics of the disease as it appeared in the 1941-1942 epidemic have been well described by Hogan and Crawford,[1] Braley,[2] and Holmes.[3] My own experience has been limited to approximately 90 cases about equally divided between the two epidemics. In these cases the disease was characterized by an acute onset with preauricular adenopathy, by the nonpurulent character of the exudate, and by the development in most cases of small, round, subepithelial corneal opacities after an interval of from 7 to 10 days.

The conjunctival involvement varied from a follicular hypertrophy in mild cases to a severe pseudomembranous, or occasionally membranous, conjunctivitis in severe cases. The corneal complications varied similarly from mild involvement without visual impairment to severe involvement with reduction of vision to 20/200 or even less. The severity of the corneal involvement did not always parallel the severity of the conjunctival involvement.

In most cases the vision eventually returned to normal but occasionally the lowered acuity persisted. This was apparently related to the diffuseness of the infiltration since persistent round infiltrates were often associated with normal vision.

There were a number of severe cases in which multiple petechial hemorrhages in the skin occurred. Coincidental respiratory symptoms were observed in a small percentage of cases and the complaint of headache at onset was common enough to suggest the possibility of meningeal irritation. In the 1947-1948 epidemic in California there was a noteworthy degree of mental depression among the patients during the first few weeks of illness.

The clinical diagnosis of epidemic keratoconjunctivitis can be made with certainty only after the development of the characteristic round, subepithelial infiltrates, but a presumptive diagnosis can be made on the basis of the clinical picture of an acute follicular conjunctivitis with grossly visible preauricular adenopathy, combined with the laboratory finding of a mononuclear cell exudate without significant bacteria.

Differential diagnosis must be made from the following disease entities: (1) Acute herpetic keratoconjunctivitis, (2) acute follicular conjunctivitis (Beal), (3) nummular keratitis (Dimmer), (4) inclusion conjunctivitis, and (5) acute trachoma. Table 1 illustrates the essential points of difference among these conditions. It will be observed that acute herpetic keratocon-

junctivitis offers the greatest difficulty. Its gross resemblance to epidemic keratoconjunctivitis is striking but differential diagnosis can be made readily on the basis of slit-lamp examination since the corneal lesions in the herpetic disease are invariably epithelial and those of epidemic keratoconjunctivitis invariably subepithelial.

disease in his family or among his immediate contacts, but the incidence was no greater among the epidemic keratoconjunctivitis cases than it was in a similar series of patients without the disease. It is noteworthy that the great majority of patients in this group were young, active adults who were in contact with numerous people in

PERSONAL OBSERVATIONS ON EPIDEMIOLOGY

An attempt was made in every case observed to work out the source of infection. The fact that the incubation period is usually from 7 to 10 days helped in tracing possible contacts. The cases could be divided into five epidemiologic groups, as follows:

1. SOURCE OF INFECTION UNKNOWN

Patients in this group could not recall having been in contact with anyone with inflamed eyes, nor had they, within the period of incubation, been in attendance at any doctor's office where they might have been accidentally exposed. In view of the possibility that the infection may be carried in the respiratory tract, each patient was questioned as to the presence of respiratory

their work or in traveling to and from their work; there was not one who was not exposed repeatedly to persons other than those in his immediate family.

2. FINGER-TO-EYE TRANSMISSION

This type of transmission was presumed to be the cause of the infection of three ophthalmologists, each of whom contracted the disease after treating one or more typical cases of it.

Case 1. Ophthalmologist A had 17 cases in his practice and developed a fulminating case of epidemic keratoconjunctivitis with thick membranes. The character of the membranes was such as to suggest diphtheria, but repeated cultures failed to reveal pathogenic bacteria. It was not until the typical corneal picture of the disease developed that

a definite diagnosis was made. In handling his cases, this ophthalmologist had used the ordinary hand-washing technique. No solutions had been used in his eyes. His wife subsequently contracted a mild case of the disease.

Case 2. Ophthalmologist B had five cases of typical epidemic keratoconjunctivitis in his practice and developed a severe case of the disease shortly after going on vacation. He had employed the usual soap and water hand wash after treating his cases. No secondary cases developed in his family.

Case 3. Ophthalmologist C developed a severe case of epidemic keratoconjunctivitis after seeing only one case, the nature of which he had not recognized until corneal signs developed. He also had employed the usual soap and water hand-washing technique. No secondary cases developed in his family.

None of the three ophthalmologists recalls rubbing his eyes after seeing cases, but this is a very common gesture and often an unconscious one. Fingers-to-eyes is believed to have been the most likely route of infection.

In addition to these three ophthalmologists seen by me personally in the 1947-1948 epidemic, I know of eight other such cases and there must surely have been still others. With reference to the 1941-1942 epidemic, I was able to obtain from colleagues and from the literature the history of seven infections in ophthalmologists. Except for one doctor whose eyes were accidentally sprayed with irrigating fluid, all were apparently the result of finger-to-eye transmission.

3. FAMILIAL TRANSMISSION

Three cases were observed in which it was clear that the husband had transmitted the disease to his wife. One of these transmissions was from one of the ophthalmologists mentioned above. The infection developed in his wife 17 days after the onset of his own disease. The wife had not treated her husband's disease in any way but she

was in intimate contact with him during the period of his illness. The exact mode of transmission could not of course be determined, but of the articles handled by both, sheets and pillowcases would seem to have been the most likely agents of transmission in view of the abundant tearing characteristic of the infection.

The other two husband-to-wife transmissions were comparable. Both couples slept in double beds where contaminated linen would have offered a likely means of transmission.

4. INDUSTRIAL INFECTIONS

During 1947 and the first four months of 1948, I observed only one individual with the disease who was employed in the shipbuilding industry. There were no other cases in this man's shop and he is believed to have contracted the disease while being treated for chronic conjunctivitis in a doctor's office in which numerous typical cases of epidemic keratoconjunctivitis were being seen.

Other patients with the disease were engaged in the following occupations: canning, meat packing, plumbing, merchandising, agriculture, law, insurance, grocery store clerking, secretarial work, and nursing. Except in the case of the one nurse and one secretary, no history of contact with other cases in connection with the patient's work could be obtained. The nurse was a public health worker who was exposed to a number of individuals with inflamed eyes but she did not know that a diagnosis of epidemic keratoconjunctivitis had been made in any of them. The secretary was employed in an internist's office and was in contact with several patients infected with the disease.

In returns from questionnaires sent to representative ophthalmologists throughout the country, there were no histories of outbreaks in any occupational group except the physician group. I was unable to elicit any history of the disease in welders or shipyard workers. This was, of course, sharply at variance with the situation in 1941-1942

when the disease was epidemic among ship-yard workers, and in particular among weld-ers.

5. OFFICE INFECTIONS

Transmission of epidemic keratoconjunc-tivitis in offices and industrial clinics has been noted repeatedly in the literature. Such

these the only common factor was the ad-ministration of a 0.5-percent pontocaine solu-tion from a dropper bottle. Tonometry and hand contamination could also have been factors in some of the transmissions. The majority of the 14 were glaucoma cases in which tonometry had been performed, but all 14 had received the pontocaine solution

TABLE 2

CASES OF EPIDEMIC KERATOCONJUNCTIVITIS DEVELOPING IN OFFICES A AND B

	Office A		Office B	
Patients developing epidemic keratoconjunc-tivitis after receiving 0.5-percent ponto-caine solution from dropper bottle	14		42	
Percentage of those exposed to solution who developed infection	90 to 100%?		98%	
Patients developing infection who had *not* been exposed to contaminated solution	5		0

Patients developing (a) keratitis (b) pseudomembranes (c) preauricular adenopathy (d) bilateral disease (e) secondary infection (f) dendritic keratitis or lid vesicles	21 2 21 18 0 1	100% 10 100 90 0 5	42 3 36 37 0 0	100% 3 85 90 0 0
Role of trauma	Tonometry, meibomian gland expression, removal of su-tures, or other manipulation in all but one case		Tonometry in majority of cases	

accidental transmissions were not uncommon in the 1941-1942 epidemic and they occurred again with important frequency in the 1947-1948 outbreak. I have seen in consultation patients from four series of accidental office transmissions and have been informed of a number of other series. Three colleagues were kind enough to furnish details of office transmissions in which the mechanism of transmission could be worked out with rea-sonable reliability. These are reported as fol-lows:

Office A. In Office A (table 2) there were 19 infections, all believed to have been de-rived from a single case. In the first 14 of

and some the pontocaine only. How long the pontocaine remained infective could not be determined as the solutions were discarded and the bottles sterilized at irregular but frequent intervals. Unfortunately there was no record of the day upon which this had been done. However, the epidemiologic data indicate that all infections occurred on one day, since the first 14 cases were seen on a single day and all developed first symptoms nine days later.

On the ninth day several of the 14 cases appeared in the office for treatment. When the first appeared, the probable source of his infection was surmised and the dropper bot-

tle technique of administering the pontocaine solution was promptly discarded. In spite of this precaution, five new cases developed after another 9-day interval. Neither pontocaine solution nor tonometry could have been the agents of transmission in any of these cases. The hands of the attending ophthalmologist could have been responsible, or possibly the arms of the treatment chairs could have been contaminated. One of the five cases did not enter a treatment room, however, but received euphthalmine drops for funduscopy in the darkroom where it is believed none of the infected patients had been.

Two additional cases were treated in this office at this time, both of them contracted secondarily by the spouses of 2 of the 19 office infections.

Office B. The accidental infections which occurred in Office B (table 2) numbered 42 and, unlike those in Office A, all cases had received 0.5-percent pontocaine solution from a single dropper bottle over a period of eight days. A good many cases had been subjected to tonometry but the only factors common to all were the use of pontocaine and examination in the treatment room. Since no patient examined in the treatment room who did not receive pontocaine developed the infection, it would seem reasonable to eliminate these other factors from consideration.

Unlike the situation in Office A, there were no known secondary infections from any of the office cases. The reported incubation period of 7 to 10 days is at variance with the sharp 9 days observed in Office A, but more careful scrutiny of the data on this point might yield closer agreement.

Office C. The infections which occurred in Office C furnished particularly valuable data on the epidemiology of the disease. The incubation period varied from 8 to 13 days in the 11 cases in which it was known, as follows: 8 days in 3 cases, 10 days in 3, 11 days in 3, 12 days in 1, and 13 days in 1. It is of interest that in those cases in which

only one eye was treated in the office, only that eye initially developed the disease; whereas, in the patients who had had both eyes treated, bilateral infection occurred. This would seem to indicate a high degree of susceptibility to the virus. All the cases which developed in this office had preauricular adenopathy and keratitis. If the cocaine-adrenalin used in the first office patient with epidemic keratoconjunctivitis was contaminated with the virus, the duration of its infectivity must have been protracted, since the first office infection did not receive the drops until 11 days later and the last infection in the first series did not receive them until 41 days later.

The following paragraphs present the reconstructed history of the 3 small outbreaks of the disease which occurred in Office C:

Series 1 (1941)

Case 1. September 7th. Patient was treated for what appeared to be an acute catarrhal conjunctivitis, left eye. The eye was cocainized and conjunctival scraping taken and found to be negative. Patient was not seen again until October 19th when there were numerous infiltrates, left eye, typical of epidemic keratoconjunctivitis. It is probable that this infection had just developed when patient was first seen in early September.

Case 2. September 18th. Patient was refracted in the office. Eleven days later (October 1th), onset of typical epidemic keratoconjunctivitis with preauricular adenopathy and corneal infiltration, both eyes.

Case 3. September 24th. Foreign body removed from upper tarsal conjunctiva. Eight days later (October 2nd), onset of conjunctivitis; developed into typical epidemic keratoconjunctivitis.

Case 4. September 25th. Conjunctival concretions in the right eye were removed. Eight days later (October 3rd), onset of conjunctivitis, right eye; developed into typical epidemic keratoconjunctivitis, later spread to left eye.

Case 5. October 6th. Abrasion of con-

junctival follicles, left eye. October 14th (8 days later) conjunctivitis started in left eye, developed into typical epidemic keratoconjunctivitis.

Case 6. October 8th. Chalazion operation, right eye. Eleven days later (October 19th), typical epidemic keratoconjunctivitis developed.

Case 7. October 18th. Mild conjunctivitis, both eyes. October 29th (11 days later) epidemic keratoconjunctivitis developed in both eyes.

Between November 1st and January 1st there were four more cases, seemingly not connected with one another, but in this period there were no office infections.

Cases 3, 4, 5, and 6 received cocaine-adrenalin drops which could have been from the same source as those used on September 7th on Case 1. However, Cases 5 and 6 had minor surgery and Case 7 an examination for conjunctivitis on days when Cases 2, 3, and 4 also made office calls. Cocaine-adrenalin drops were used in Cases 1, 3, 4, 5, and 6, and in all 7 cases there was manipulation of the lids.

Series 2 (1947)

Case 1. June 17th to 21st. An eye physician with bilateral epidemic keratoconjunctivitis was seen in consultation in Office C.

Case 2. June 17th. Tear duct, right eye, irrigated because of complaint of tearing. First sight of conjunctivitis, right eye, June 26th. Typical epidemic keratoconjunctivitis developed.

Case 3. June 21st. Patient prepared for cataract operation: tear duct irrigated, tension taken, meibomian glands massaged. Cataract operation, June 22nd. Conjunctivitis started July 1st, developed into typical epidemic keratoconjunctivitis.

Case 4. June 21st. Exactly like Case 3.

All four cases received cocaine-adrenalin drops. Evidently Cases 2, 3, and 4 were office infections, from these drops or from contaminated hands. However, since the attending ophthalmologist had diagnosed

Case 1 as epidemic keratoconjunctivitis, he was very careful about his hand washing technique and therefore considers the infectious agent to have been in the drops or on the nipple of the dropper bottle. It is his opinion that the virus probably stays viable for hours or days on the rubber nipple, in the drops, or on the hands.

Series 3 (1947)

Case 1. September 20th. Right eye became inflamed about 10 days after an eye examination by an ophthalmologist in Office X; vision became blurred around October 1st. Observed in Office C on October 19th when there were numerous subepithelial infiltrates, both eyes.

Case 2. October 26th. Friend of Case 1 consulted same ophthalmologist in Office X. First observed in Office C on November 7th when numerous corneal infiltrates had developed in both eyes.

Case 3. November 23rd. Patient examined in Office X. First observed in Office C on December 13th when there were a few superficial punctate infiltrates.

All three of these patients developed typical epidemic keratoconjunctivitis which in all probability they acquired in Office X between September 10th and November 23rd.

EPIDEMIOLOGIC CONTROL

The information regarding the epidemiology of epidemic keratoconjunctivitis is admittedly incomplete due to lack of laboratory controls. Until the incidence of neutralizing antibodies for the virus in the general population is known, little can be said concerning inapparent or subclinical infections. It is believed, however, that one attack confers a permanent immunity and it is noteworthy that it has been impossible to obtain a history of a second attack from any of my own cases or from the records of my colleagues. The data from the office infections reported above indicate that there is a high degree of susceptibility in the gen-

eral population and would suggest that subclinical infections are rare.

On the basis of the experience gained in the 1941-1942 epidemic, a number of recommendations for the prevention of the disease were promulgated[4-7] but unfortunately were not generally adopted. Of these recommendations, the following would seem to be the most important:

1. Not only ophthalmologists, but general physicians and nurses, particularly those connected with industrial dispensaries, should become thoroughly familiar with the clinical characteristics of the disease in order to facilitate early diagnosis.

2. Physicians and nurses should be meticulous in the washing of their hands between examinations. This washing should be with soap and water and could well include scrubbing with a brush.

3. Dropper bottles should be discarded from all eye offices and industrial dispensaries. Individual sterilizable droppers should be used routinely.

4. Office procedures should be modified so that epidemic keratoconjunctivitis cases can be seen apart from other cases. Protection against contamination of treatment chair arms and doorknobs should be instituted.

5. All instruments, including tonometers and contact lenses, which are used on patients should be sterilized.

6. Patients with epidemic keratoconjunctivitis should receive instruction in the use of tissues in eye care to prevent hand contamination. Separate sleeping arrangements should serve to diminish husband-and-wife infections.

7. Common use of masks and goggles in industry should be discouraged.

DISCUSSION

The literature on epidemic keratoconjunctivitis reveals a considerable degree of confusion as to the relationship of the disease to superficial punctate keratitis, nummular keratitis, acute follicular conjunctivitis

(Beal), and herpetic keratoconjunctivitis. The work of Sanders[3] has shown clearly that epidemic keratoconjunctivitis is a specific virus disease. Future laboratory studies will no doubt clarify the picture, but on clinical grounds alone a reasonable differentiation is possible at the present time.

Superficial punctate keratitis, as we are familiar with it in the United States, is an entirely different disease,[9] with minimal conjunctival symptoms and a chronic course. The punctate corneal lesions are not grossly visible like the round infiltrates of epidemic keratoconjunctivitis and are epithelial rather than subepithelial. It is true that epidemic keratoconjunctivitis was originally described by Fuchs[10] under the name "superficial punctate keratitis," but usage in this country has identified this name with a disease entity of which it is more closely descriptive.

The term "keratitis nummularis," although originally identified with the entity now known as epidemic keratoconjunctivitis, has since been used to describe a quite different disease[11] with insignificant conjunctival lesions compared with the corneal lesions, and with a tendency of many of the corneal infiltrates to form facets and even ulcers, a tendency entirely lacking in epidemic keratoconjunctivitis.

Acute follicular conjunctivitis (Beal) has, in my experience, never been complicated with keratitis. It has a shorter course than epidemic keratoconjunctivitis (never longer than three weeks), moreover, and has never been known to develop pseudomembranes or grossly visible preauricular adenopathy.

Herpetic keratoconjunctivitis is a rare disease in which the conjunctival signs exactly simulate those of epidemic keratoconjunctivitis but in which the corneal signs develop without the delay characteristic of epidemic keratoconjunctivitis and are epithelial rather than subepithelial. The occurrence of a dendritic figure is of course differentiating. The studies of Maumenee and his associates[12] suggest a relationship between

this herpetic disease and epidemic keratoconjunctivitis but their work has yet to be confirmed.

Epidemic keratoconjunctivitis is not the only infection in which transmission has occurred in offices and clinics. The role of the tonometer in the transmission of inclusion conjunctivitis has been described (Thygeson and Stone[13]) and the role of the contaminated solution bottle in the production of pyocyaneus ulcers has been well established (McCulloch[14]). No other infection has produced such widespread office outbreaks, however, and no other disease has produced a comparable number of infections in doctors and nurses. It is obvious that a thorough reëxamination of office and dispensary techniques is indicated.[6]

The mechanism of spread in office outbreaks is not difficult to work out but the epidemiology of sporadic cases is obscure. Does the lack of known contact with typical cases indicate that subclinical disease is a factor? Elucidation of this question must await further laboratory studies on the general population. On purely clinical grounds, however, it seems within the realm of the possible that a single case of epidemic keratoconjunctivitis could contaminate enough doorknobs, toilet levers, washbasin faucet handles, drinking fountain handles, and so on, to account for sporadic cases of the disease over a wide territory.

SUMMARY AND CONCLUSIONS

1. Epidemic keratoconjunctivitis, which first appeared in the western United States in epidemic form in the fall of 1941, became widespread throughout the country in 1942. During the war years of 1943-1946 only sporadic cases were seen and, contrary to expectation, the disease did not become a military problem. In 1947, the disease again became epidemic in California and, to a lesser extent, in other parts of the country.

2. The American disease is believed to be identical with the keratoconjunctivitis first described in Vienna, in 1889, under different names by Adler, Fuchs, and others. It should be differentiated from acute herpetic keratoconjunctivitis, nummular keratitis (Dimmer), acute follicular conjunctivitis (Beal), acute trachoma, and so on. It bears no relationship to superficial punctate keratitis, an entity which has been widespread in this country.

3. The high communicability of the disease appears to be due to the ability of the virus to survive drying and dilution. In this respect it differs from other potentially epidemic types of keratoconjunctivitis such as gonorrheal ophthalmia and trachoma.

4. In the present study, transmission of the disease has been shown to have occurred by the following means: (a) contaminated tonometers, (b) contaminated solutions, including pontocaine, cocaine-adrenalin, and homatropine, (c) direct finger-to-eye transmission, and (d) fomites, especially welders' masks, goggles, and common tools.

5. No satisfactory evidence was obtained to indicate the presence of asymptomatic conjunctival carriers or respiratory carriers.

6. In view of the high frequency of office transmissions, routine office practice should be reëxamined in order to prevent this and other infections. The following prophylactic measures are to be recommended: (1) The discarding of all dropper bottles, (2) the use of individual sterilizable droppers, (3) adequate hand washing before and after treatments, (4) the use of disposable treatment chair arm covers, and (5) individual masks and goggles for workers in industry, with early recognition and isolation of cases.

87 North 6th Street.

ACCOMMODATIVE DEFECT FOLLOWING ATMOSPHERIC CONCUSSION*

HOMER E. SMITH,† M.D.

Salt Lake City, Utah

The effects of atmospheric concussion on the ocular structures have long been recognized. Stoewer,[1] as cited by Wurdemann,[2] described a multiplicity of ocular pathologic findings resulting from concussion following the terrific explosion at the Roburit factory long before World War I. During and following World War I, Lagrange,[3] McKee,[4] Tooke,[5, 6] deSchweinitz,[7] Doherty,[8] Anderson,[9] Lister,[10] Slight and Haughey,[11] and others[12, 13] rather extensively covered the subject matter pertaining to ocular lesions resulting from atmospheric concussion in military and civilian casualties seen by them during that war.

The effects of atmospheric concussion on the eye during World War II have been described by Stallard,[14] Mathews,[15] Tyrrell,[16] and others.[17-29] However, in spite of the extensive writings to date, manifestations of doubt as to the efficiency of atmospheric concussion (windage) in producing ocular damage appear in the literature.[28-29]

The studies of Theis,[30] Sutherland,[31] and others,[32-35] have shown the essential damaging physical qualities of atmospheric blast to be: (1) An excessively intense longitudinal compression wave of short duration travelling at a velocity of 5,000 to 25,000 feet per second, with a pressure component up to 200 atmospheres (3,000 pounds) per square inch, followed by (2) a phase of rarefaction (suction component) which is never less than 15 pounds per square nich (perfect vacuum). Both components are capable of producing injury.

It is natural that the eye should share, with other organs, the damage sustained by concussion. In the absence of gross lesions, minor changes may be found in the ocular structures which are of value to the ophthalmologist in his clinical evaluation of patients who fall into this postconcussion class.

Many articles have been presented recently[36-45] describing the cerebral and mental effects following atmospheric or blunt traumatic concussion, and their manifestation following such exposure has become known as the "postconcussion state."[44] The essential symptoms that have been described in this syndrome are: headache, dizziness, fatigability, impairment of memory, poor concentration, sensitivity to temperature change, character changes, emotional instability, and antisocial behavior.

Among service personnel (the source of this material) other motivating factors were effective in precipitating similar emotional and personality disturbances. To rule out these in patients who had a history of exposure to atmospheric concussion, a search was made for objective evidence of ocular pathologic conditions which might have resulted from such trauma.

While I was on active duty in the U.S. Navy Medical Corps, many such postconcussion cases were observed in which relatively minor pathologic ocular findings appeared to substantiate a history of exposure to atmospheric concussion of traumatizing degrees. The patients had been hospitalized on the neuropsychiatric service with the complaints of irritability, restlessness, inability to concentrate, lassitude, periodic emotional swings, memory deficiency, headaches, rapid ocular fatigue and pain upon reading, blurred vision, ocular pains, and ear symptoms of tinnitus and pain. They were referred to the department of ophthalmology by the neuropsychiatric service for evaluation of their eye complaints. These cases presented evidence of mild but definite ocular changes in comparison with those seen in severe concussion injuries. Although minor in degree of severity, they were uniformly consistent and of such constancy as to offer definite aid in their analysis for the neuropsychiatric service.

CASE REPORTS

Four such cases are presented and, in Case 1, a 20-month follow-up examination was made.

CASE 1

History. A 35-year-old lieutenant was admitted to the hospital on October 10, 1943, with the complaints of diminished hearing, numbness, marked fatigue, stuttering, memory defect, mental lethargy, emotional instability, insomnia, speech difficulty, occipital headaches, blurred distant and near vision, poor night vision, and bilateral eye pains since exposure to a severe bomb blast on October 1, 1943.

The physical examination was essentially negative except for the significant aural, neuropsychiatric, and ocular findings. His hearing was reduced

and bone conduction exceeded air conduction.

The neurologic findings revealed an increase in the deep tendon reflexes on the left, a questionable positive Babinski on the right, some impairment of coördination in the use of the upper extremity muscles, mental slowness, confusion in executing instructions, and hesitancy in selecting words for speech. It was the opinion of the neurologist that there was present a diffuse organic condition simulating the picture of multiple sclerosis which could have been due to multiple areas of edema or hemorrhage resulting from the concussive effects of the explosion.

The psychiatric consultant reported, "In my opinion this man shows a very appreciable personality change of the type associated with concussion. These changes are regressing, but I am certain a Rorschach test, even at the present time, would reveal an organic pattern. I believe this man is unfit for combat duty, and should be under prolonged neuropsychiatric observation because of the possibility of (1) marked personality changes and (2) convulsive episode."

The eye findings revealed a mild degree of episcleral injection near the limbus of each eye. Vision was: O.D., 20/25; O.S., 20/30. With a pinhole disc the vision of each eye was reduced to 20/40. Unfortunately, accommodation measurements were not taken. The homatropine cycloplegic refraction revealed: O.D., with a +0.75D. sph. $\subset$ +0.5D. cyl. ax. 80° = 20/20; O.S., with a +0.75D. sph. $\subset$ +0.25D. cyl. ax. 100° = 20/30.

The ophthalmoscopic examination revealed hazy media, pigment clumps on the anterior lens capsule, and fine products of inflammation in the vitreous. The discs were slightly elevated, the margins blurred, and the central excavation was filled with white edematous tissue. The retinas showed diffuse edema throughout the whole of the fundi, being especially marked in the equatorial and peripheral regions. In these regions there were also areas of mild exudative choroiditis. In the right fundus, one disc diameter temporal and down from the macula there was a one-fourth torsion of the edematous retina and its vessels with a small hole. The maculas showed fine edema, distortion of the foveal reflex, and mild retinal pigment epithelium proliferation.

The visual fields revealed a peripheral constriction to a 2-mm. white target at 330-mm. distance which varied from 15 to 25 degrees in extent (fig. 1). X-ray films of the skull were negative.

Course. Three weeks later the patient was transferred to another hospital and was returned to full duty on December 31, 1943.

Follow-up study. On August 14, 1945, the patient was again admitted to a naval hospital with the chief symptoms of emotional swings, mood changes, lack of interest, and personality changes. The physical examination was essentially negative.

Eye findings. Corrected vision was 20/20 in each eye with the homatropine cycloplegic refraction findings of: O.D., +0.25D. sph. $\subset$ +0.75D. cyl. ax. 75° = 20/20; O.S., −0.25D. sph. $\subset$ +1.0D.

cyl. ax. 95° = 20/20. The amplitude of accommodation was: R.E., 3.3 diopters (30 cm.); L.E., 5.9 diopters (17 cm.). The peripheral and central fields to a 3-mm. white target were normal. A slight ptosis of the right upper lid existed, and the right pupil responded more to cocaine pupillary studies than the left. Versions and phorias were within normal limits.

The fundi revealed the discs to be round, flat, with distinct margins and tissue proliferation in the physiologic cups. The vascular structure appeared to be normal. The maculas showed fine pigmentary changes, distorted foveal reflexes, and

1945, with the complaints of frontal headaches, chest pains, antisocial attitude, restlessness, nightmares, inability to concentrate, blurred vision on detailed use of the eyes, and earache.

The past history (medical records substantiated the patient's story) revealed that on February 19, 1945, while on Iwo Jima, the patient was knocked unconscious for an indefinite period as a result of blast concussion (mortar-shell explosion). Upon awakening, the patient was unable to hear or speak and noticed great difficulty in reading. The hearing began to improve in 24 hours, but the speech defect persisted for 6 days. The record states that
Fig. 1 (Smith). *Case 1*. Visual fields, taken on November 2, 1943, revealed a peripheral constriction to 2/330 white.

reflexes radiating out from their center like spokes in a wheel.

The retina in the right eye revealed a small proliferating retinal scar lying between two anomalously directed blood vessels that were incorporated in the "whorl" of the previous findings. From this scar, radiated additional spokelike reflexes.

In the equatorial region and periphery there were diffuse omnipresent fine retinal pigmentary changes of dispersion and proliferation. Associated with them were definite, fine changes in the retina which appeared to be cystic in nature and which rendered the tissue somewhat translucent.

The laboratory findings were essentially normal. The spinal fluid showed: W.B.C., 2; R.B.C., 3; sugar, 62 mg. per 100 c.c.; protein, 30.2 mg.; chlorides, 790 mg.; globulin, faint trace; negative Kahn; colloidal gold curve, 1,123,210,000. An electroencephalogram tracing was within normal limits.

CASE 2

History. This 23-year old white, Marine combat man was admitted to the hospital on July 5,

there was no evidence of marked emotional disturbance.

The family history was essentially negative.

The physical examination revealed the following significant findings. There was a 40 percent hearing loss in the left ear and Shrapnell's membrane was red on the left side.

Eye findings. Vision was: O.D., 20/20; O.S., 20/25, and the amplitude of accommodation was 2.4 diopters (42.3 cm.) in the right eye and 2.3 diopters (44 cm.) in the left eye.

The cycloplegic (homatropine hydrobromide) refraction was: O.D., +0.75D. sph. ⊃ +0.25D. cyl. ax. 95° = 20/20; O.S., +0.5D. sph. ⊃ +0.37D. cyl. ax. 80° = 20/20. Versions and phorias were within normal limits. His PcB. was 25.5 cm. Perimetric studies were normal. The external ocular examination was essentially normal and slitlamp findings were within normal limits.

The fundi revealed the media to be clear, the discs were round, flat, and had distinct margins. There was increased visibility of the fine vessels. The appearance of the retinas, as a whole, was

that of semitranslucence from edema. In the equatorial regions and periphery, the edema increased in degree to produce moth-eatenlike areas of graywhite retinitis, irregular in shape and size, which were deep in the retina as determined by parallax. Diffuse, small, retinal pigment clumps were present. In the choroid, evidence of mild healed choroiditis was present and, in the left eye, a disc-sized hemorrhage was present in the peripheral choroid below. The maculas appeared to be normal.

The laboratory findings were essentially negative.

The neuropsychiatric consultation revealed no

of a mortar-shell explosion 10 feet from him. The patient stated that he was unconscious for 12 hours following the trauma. There had been gradual improvement in his condition since then.

The authenticated past history revealed that the patient was first admitted to the sick list with the diagnosis of "blast concussion, atmospheric," on February 19, 1945, with the symptoms as he described. He continued as a patient in the naval medical facilities until May 23, 1945, at which time he was discharged to limited duty. The family history was essentially normal, as was the general physical examination.
Fig. 2 (Smith). *Case 3.* Visual fields, taken on September 19, 1945, showed a 15-degree constriction to 3/330 white.

neurologic disturbance. The psychiatric evaluation revealed, "a coöperative but tense individual with normal speech. Combat rumination is interfering with thought processes. Affect is appropriate and grasp good. Service history confirms a severe blast concussion syndrome in February, 1945, on Iwo Jima with neuropsychiatric disability at that time. His present eye and somatic pain plus thought irregularity, are considered due, in the main, to his recent organic brain injury. Unfit for service of indefinite duration and recommend that he be discharged from the U.S. Naval Service."

CASE 3

History. The patient, a white man, aged 20 years, was a private first class in the U.S. Marine Corps, who was admitted to the hospital on September 17, 1945, with the complaints of a shaky feeling, headaches, rapid ocular fatigue when reading, general fatigability, and restlessness during sleep. These symptoms had begun 7 months previously, following exposure to the concussion

Eye findings. Vision was: O.D., 20/20; O.S., 20/20. Cycloplegic (homatropine hydrobromide) refraction revealed: O.D., +0.75D. sph. ⊃ +0.25D. cyl. ax. 100° = 20/20; O.S., +0.75D. sph. ⊃ +0.37D. cyl. ax. 80° = 20/20. The amplitude of accommodation was: R.E., 7.7 diopters (13 cm.); L.E., 6.9 diopters (14.5 cm.).

The fundi presented a slight but definite appearance of retinal edema in the periphery with the findings in the right eye being the most marked. Fine pigment changes were present in the pigment epithelium. Versions and phorias were within normal limits. Peripheral field (fig. 2) studies with a 3-mm. white target revealed a 15-degree constriction from normal.

The neurologic examination was negative and the psychiatric examination revealed mild mental tension, anxiety, and sleep disturbance. The patient was continued on limited active duty.

CASE 4

History. This 24-year-old Marine corps ser-

geant (white) was admitted to the hospital on November 5, 1945, for reëvaluation of his symptoms of restlessness, irritability, and nightmares.

His authenticated past history revealed that on November 15, 1944, he suffered trauma to both eyes and head from "blast concussion, atmospheric," as a result of a hand grenade exploding directly in front of him. This incident was followed by tinnitus, ocular pain, and headache. In January, 1945, the patient began to show mental symptoms of nervousness, restlessness, irritability, and sleeplessness. In February, 1945, he was admitted to the sick list because of accentuation of these symptoms

The neuropsychiatric examination revealed residual evidence of his occupational fatigue and it was felt that he was not qualified for full duty (fig. 4).

DISCUSSION

The major damage sustained by the eyes as a result of exposure to atmospheric concussion has been elaborated upon in the past; however, the effect upon the ocular tissues of relatively minor degrees of atmospheric
Fig. 3 (Smith). *Case 4.* Visual fields, taken on March 22, 1946, showed a slight peripheral constriction to 2/330 white.

and was ultimately placed on limited active duty in the United States on April 18, 1945, with a diagnosis of "fatigue, operational." The physical examination at this time was essentially normal.

Eye findings. Vision was: O.D., 20/20; O.S., 20/20. Cycloplegic (homatropine hydrobromide) refraction showed: O.D., +0.75D. sph. = 20/20; O.S., +0.75D. sph. ⊃ +0.12D. cyl. ax. 90° = 20/20. The amplitude of accommodation was: R.E., 7.4 diopters (13.5 cm.); L.E., 7.2 diopters (13.8 cm.). The PcB. was 8.5 cm.

The external ocular examination and pupillary findings were within normal limits. The fundi revealed a diffuse pre-equatorial irregularity in the pigment epithelium. There was a translucent appearance to the retina in the periphery with areas of cystic degeneration. Occasional areas of increased and dispersed choroidal pigment were seen between the choroidal vessels which were interpreted as residue of previous choroiditis. The field studies with a 2-mm. white target showed a slight peripheral field constriction (fig. 3).

concussion producing lesser damage has been infrequently mentioned. From the cases cited above, it appears as if comparatively minor but important changes may occur in the tissues of the eye as a result of exposure to atmospheric concussion.

The changes seen in the fundi and the deficiency manifested by the accommodative apparatus were rather constant, and the latter was the apparent source of a constant symptom on the part of these patients—that is, fatigability upon reading or with close detailed work. These ocular lesions aided the neuropsychiatric department in evaluating the concussion trauma background which contributed to the psychiatric complaints of

patients who had been exposed to atmospheric concussion.

Westcott[46] and Groves[47] differ somewhat in their opinoin as to the disturbance to the

to the defect in the accommodative apparatus. The pathologic defect in the accommodative mechanism is apparently in the ciliary body, which is consistent with the fundus
Fig. 4 (Smith). Accepted limits of accommodative values for patient's age (see reference 48) compared with the accommodative findings exhibited by the patients in this study.

accommodative power of the eye resulting from blunt traumatic concussion. The more extensive work of Wescott indicates that there is no significant posttraumatic change in the accommodative amplitude; rather, the reading discomfort experienced by these patients is due to a disturbance in the higher cortical centers.

In our cases the inability to read with comfort seemed to be directly attributable

changes increasing in degree and extent as the ora serrata is approached.

SUMMARY

Four cases with authenticated histories of exposure to atmospheric concussion of undetermined degree have been presented. They had been examined at posttraumatic intervals which varied in time from 10 days

to 12 months. In one case follow-up study was made after 20 months. All cases were seen as consultations for the neuropsychiatric service for evaluation of their ocular complaints.

The cases presented the following fundamental pathologic features:

1. Symptoms of headache, irritability, inability to concentrate, restlessness, fatigability, ocular fatigue and pain upon reading.

2. Deficiency in the amplitude of accommodation.

3. Retinal edema which was more marked in the equatorial and pre-equatorial regions of the fundus.

4. Mild peripheral choroiditis lesions.

5. Cystic degeneration of the periphery of the retina.

6. Constriction of the peripheral visual fields.

CONCLUSION

Atmospheric concussion may affect the ocular structures to a variable degree. In minor degrees, there appear disturbances in the ocular structure and function which are uniformly constant. These are of aid to the ophthalmologist in evaluating the ocular complaints, and help the psychiatrist in his evaluation of the part played by the trauma in patients who manifest the symptoms of the "postconcussion syndrome."

Furthermore, there appears to be no correlation between the eye findings in the atmospheric and blunt traumatic postconcussion cases.

Atmospheric concussion may produce an ocular syndrome characterized by deficiency of accommodation, retinal edema, mild choroiditis, and peripheral field constriction.

OPHTHALMIC MINIATURE

The examination of eyes affected with fungus haematodes, in its early period, has led to the conclusion that the disease consists in organic change of the retina, or in a growth from the retinal extremity of the optic nerve. This would account satisfactorily for the appearance, exhibited in the commencement, of an adventitious growth in the fundus of the eye.

Sir William Lawrence, *A Treatise on the Diseases of the Eye*, 1833.

VERTICAL NYSTAGMUS ON DIRECT FORWARD GAZE WITH VERTICAL OSCILLOPSIA*

MORRIS B. BENDER, M.D., AND WARREN F. GORMAN, M.D.

New York

Vertical nystagmus may be present either on upward gaze or on direct forward gaze. Vertical nystagmus on upward gaze is not uncommon. As a rule, it is indicative of acquired disease of the brain stem.[1] Vertical nystagmus on direct forward gaze, however, is rare and is usually found in a patient with "congenital" nystagmus.[†]

On rare occasions, vertical nystagmus on direct forward gaze may be seen in patients with acquired disease of the nervous system. In these cases of vertical nystagmus it is necessary to distinguish the congenital from the acquired type. Although the differential diagnosis depends on a consideration of all the factors in each case, the presence of oscillopsia is frequently a deciding feature.

Oscillopsia is a visual experience in which the patient sees a stationary object as moving from side to side (horizontal oscillopsia) or up and down (vertical oscillospia). The oscillopsia is concomitant with the rhythmic movements (nystagmus) of the eyes and it is usually indicative of an acquired nystagmus. The following two case reports are studies of patients with acquired upward nystagmus on direct forward gaze.

REPORT OF CASES

CASE 1

History. E. M., a 55-year-old man, was admitted on January 2, 1948, to the Bellevue Psychiatric Hospital. For two days before

admission he felt weak and had the sensation of "falling backwards." The past medical history disclosed that in 1945 he was rendered momentarily unconscious by a blow on the head. In 1942, he had a discharge from the right ear, with subsequent tinnitus and poor hearing. He later admitted to consuming a quart of sherry wine daily.

On examination he was found to be emaciated, with dry peeling skin, fissures at the corner of the mouth, and injection of the conjunctivas with vascularization about the limbus of both eyes. There was frequent blinking, avoidance of light, and other signs of photophobia. (The patient claimed that he had always been sensitive to light.)

There was a constant tremor of the entire body, and a coarser tremor of the right lower extremity. He walked slowly on a broad base, falling to the left or backward. Both ankle jerks were diminished. There was plantar hyperesthesia and calf tenderness. Vibratory sense was diminished in both lower extremities. All laboratory studies, including spinal fluid examination, X-ray studies of the skull and chest, gastro-intestinal series, liver chemistries, blood bromides, and blood Wassermann tests, were negative.

Ocular status. There was photophobia with frequent blinking and narrowing of the palpebral fissures. Eye movements were performed well in all directions of gaze. However, when he looked directly forward, there was a very rapid nystagmus in the vertical plane. The nystagmus took place entirely above the horizontal meridian and the fast component was in an upward direction.

As the patient looked to each side, the spontaneous vertical nystagmus became oblique, inclining about 45 degrees to either side. When the patient lay on his side or

† In the congenital form, vertical nystagmus on forward gaze is not the only ocular finding. It is frequently associated with a nystagmus on lateral, upward, and downward gaze. Often in these cases there is a history that the patient has had "dancing eyes" for many years.

back, the nystagmus continued unchanged relative to the long axis of the body. Closing one eye or both eyes did not alter the nystagmus. On extreme upward gaze, however, the nystagmus increased. On downward gaze the nystagmus diminished. The nystagmus fluctuated in rate and amplitude. In time, it gradually diminished.

Subjectively, the patient reported that objects "moved up and down"—vertical oscillopsia. He said that near objects oscillated less than far objects and not as rapidly.

Special Studies

A. Vestibular Tests

1. Turning tests. The patient was placed in a Bárány chair in a sitting position, with his head inclined 30 degrees forward. With his eyes closed, he was rotated 10 times in 20 seconds to either side. In a normal individual this procedure produces horizontal nystagmus in a direction opposite to that of rotation. In this patient the Bárány test modified the spontaneous upward nystagmus, resulting in an oblique (up and out) nystagmus.

The patient's head was then inclined 90 degrees toward the right shoulder and he was again rotated to the right and left. With the head in this position, rotation of normal people to the right (clockwise) produces downward nystagmus, and rotation to the left (counter-clockwise) produces upward nystagmus. On rotating the patient in this manner to the right, it was found that the expected downward nystagmus was not present. Instead, his spontaneous upward nystagmus ceased for 15 seconds, then slowly reappeared. On rotation to the left, the preexistent upward nystagmus was increased in amplitude for 24 seconds, after which time the resting upward nystagmus became apparent at its usual amplitude.

2. Caloric tests. Aural examination revealed that there was no significant hearing loss. Each ear was irrigated for 60 seconds with ice water while the patient was sitting erect and his eyes fixating forward. Such

irrigation of the right ear produced nystagmus to the left and irrigation of the left ear produced nystagmus to the right. There were no abnormal changes on the past pointing. Vertigo was present.

B. Optokinetic Nystagmus

A drum, 9 inches in diameter, papered with one-half inch alternate black and white vertical stripes, was rotated in front of the patient's eyes at a speed of 2 revolutions per second. In normal individuals, rotation of the drum with the axis in the vertical plane results in horizontal nystagmus. In our patient such rotation produced oblique nystagmus. With the axis of the drum in the horizontal plane, downward rotation accentuated, while upward rotation diminished the spontaneous upward nystagmus.

C. Effects of Drugs.

It is known that barbiturates influence nystagmus and other ocular movements.[2] Latent nystagmus or any other type of nystagmus which is present on forward gaze is abolished by intravenous injections of sodium amytal. In a previous communication[3] it was also reported that an ocular squint disappeared whenever that patient was intoxicated with alcohol. Evidently alcohol had the same effect as barbiturates. Consequently we tried the effect of the drugs (amytal and alcohol) in our two cases of vertical nystagmus on forward gaze.

1. Sodium amytal. Sodium amytal (0.2 gm.) was injected intravenously over a period of two minutes. Within two minutes the spontaneous upward nystagmus on forward gaze stopped and the oscillopsia disappeared. Deviation of the eyes in the vertical or horizontal plane resulted in nystagmoid movements but on many occasions the nystagmoid movements were fine and rapid.[4] During the period when the nystagmus on forward gaze was abolished by amytal, there was likewise no response to the optokinetic drum on forward fixation. We did not carry out Bárány-turning or caloric-stimulation

tests while the patient was under the influence of amytal. After 11 minutes, the spontaneous upward nystagmus on forward gaze and the concomitant oscillopsia began to return.

2. *Alcohol.* The patient was given 1,000 cc. of medicinal sherry in 10 minutes by stomach tube, after a gastric analysis. He became intoxicated and showed slurred speech, cheerful affect, and an increase in staggering. His body and extremity tremor diminished. The nystagmus on forward gaze ceased completely, as did the oscillopsia. However, as in amytal narcosis, nystagmus on lateral or vertical gaze persisted.

3. *Hyoscine.* It was suggested that the spontaneous nystagmus on forward gaze might be an extrapyramidal disorder. For that reason the effect of hyoscine on ocular movements was tried. Hyoscine (1/100 gr.) was injected subcutaneously. After 35 minutes, the patient complained of a dry mouth, and showed dilated pupils and a diminution of the tremor of the extremities. However, there was no effect on the nystagmus.

Course. The patient was given large doses of water-soluble vitamins orally and liver extract intramuscularly. The nystagmus fluctuated in rate and amplitude from day to day, but gradually subsided. Although, originally, lateral deviation of the eyes had resulted in oblique nystagmus, after 9 weeks lateral gaze produced largely horizontal nystagmus. The spontaneous vertical nystagmus above the horizontal meridian on forward gaze gradually diminished in rate and amplitude, being almost imperceptible 13 weeks after admission to the hospital. The peripheral neuropathy improved gradually.

Comment. This patient, a known alcoholic, showed vertical nystagmus and vertical oscillopsia on forward gaze. Under observation the nystagmus and the oscillopsia subsided, thus suggesting that the ocular signs and symptoms were of the acquired type. Of interest is that amytal given intravenously and alcohol by mouth temporarily abolished the vertical nystagmus on forward gaze and the associated oscillopsia.

CASE 2

History. W. T. M., a 48-year-old white carnival operator, was admitted on October 8, 1947, to the Bellevue Psychiatric Hospital with early delirium tremens. On October 2, 1947, he noted that objects "jumped up and down"—(oscillospia)—"that the room seemed to turn around" and that he "saw double both to one side or above." He complained of dizziness and blurred vision. He also volunteered that "when one doctor examined me down here I couldn't turn my eyes to the left at all," thus suggesting a paralysis of conjugate gaze to the left.

Routine examination revealed signs of diffuse involvement of the entire nervous system. Defects in recent memory were present. There was a coarse irregular jerky tremor of all extremities. There were signs of peripheral neuropathy with absent knee and ankle jerks, diminished vibration sense below the knees, hyperesthesia to pin prick in the glove and stocking areas, calf tenderness and hyperpathia on stroking of the plantar surface of the feet.

All laboratory examinations, including spinal fluid studies, X-ray studies of the chest and skull, electroencephalogram, blood count, urinalysis, blood bromides, blood and spinal fluid Wassermann tests, and liver chemistry tests, were within normal limits. Gastric analysis showed that there was no free acid. It should be noted that the patient had had a subtotal gastrectomy for peptic ulcer three months before the present admission.

Ocular status. The patient was transferred to the neurologic service on October 10, 1947. He was observed daily during his hospital stay and at frequent intervals thereafter for a total of 9 months. Special eye examinations were periodically performed. It was noted that when the patient looked straight ahead the eyes moved rhythmically up and down (vertical nystagmus). The excursions

occurred entirely above the horizontal meridian and the quick component was in an upward direction. The eyelids moved in synchrony with the upward nystagmus. Position of the head did not alter this nystagmus. Subsequent examinations showed that with the head erect, lateral deviation of the eyes was also accompanied by an upward nystagmus but frequently there were rotary components.

On forward gaze there was also spontaneous zig-zag rotary movement of each eye, more so on the left. These zig-zag movements in one eye were neither coördinated nor associated with the movements in the other. Similar, almost myoclonic, movements were noted in various muscles throughout the body, especially in the tremulous upper extremities. On extreme downward gaze, the vertical nystagmus stopped. On moderate elevation of gaze, the vertical nystagmus became more conspicuous but, on extreme upward gaze, the nystagmus disappeared.

Fixation of near and far objects did not alter the nystagmus on forward gaze but the oscillopsia was much more apparent to the patient when he fixed objects at a distance. There was a latent weakness of both external rectus muscles. On occasions, when he attempted to look to the left, the right eye rotated to the left, but the left eye turned inward toward the nose. The mirror image of that pattern of movement took place on his attempt at right lateral gaze.

Convergence was good. The visual acuity on admission to the neurologic service was 20/100 and within a few weeks improved to 20/30 in each eye. Examinations of the central and peripheral fields of vision for form and color were normal.

Special Studies

A. Vestibular Tests

As already noted, the patient reported that the vertical oscillation of objects diminished as they approached him. Tests with targets at near and distant points revealed that the vertical oscillopsia disappeared when he fixed

a target within one meter of his eyes. Beyond this point the vertical oscillopsia was pronounced. Bárány turning tests induced no significant abnormalities. Caloric tests, using cold-water irrigation of the ears, also yielded apparently normal reactions.

B. Optokinetic Nystagmus

On rotating a striped drum before the patient's eyes, the spontaneous nystagmus was altered. When the axis of the drum was horizontal and the rotation toward the patient,* the amplitude of the upward nystagmus was increased. When the direction of rotation of the drum was reversed, the eyes dipped below the horizontal axis and the upward nystagmus diminished in amplitude. On rotation of the drum in the vertical axis before the patient's eyes, clockwise or counter-clockwise rotation produced oblique (up and out) modification of the spontaneous vertical nystagmus.

C. Effect of Drugs

1. Sodium amytal. About two minutes after intravenous injection of 0.25 gm. of sodium amytal, the nystagmus on forward gaze began to decrease in amplitude. The vertical nystagmus on direct forward gaze disappeared completely 12 minutes after the injection was begun and remained absent for a period of 13 minutes. The oscillopsia likewise disappeared during this period. The zig-zag and completely dissociated eye movements were also abolished by amytal.

2. Alcohol. Intravenous injection of 80 cc. of ethyl alcohol, equivalent to 5 ounces of whiskey, caused the vertical nystagmus on forward gaze to disappear. The nystagmus on upward and lateral gaze, however, became more marked in amplitude. There were oblique components on lateral gaze. By the time tests with alcohol were made, the zig-zag eye movements were no longer present.

---

*In the normal individual such rotation of the drum produces slow deviation of the eyes above the horizontal axis with upward nystagmus.

Therefore, we have no information as to the effect of alcohol on these movements.

Course. Under observation the vertical nystagmus on forward gaze subsided and ultimately disappeared after 8 weeks. There was a concomitant disappearance of the vertical oscillopsia on forward gaze. Vertical nystagmus on forward gaze persisted for 12 weeks. Horizontal nystagmus on lateral gaze was still present after 5 months. Seven months after admission, there was slight rotatory nystagmus on left lateral gaze.

The peripheral neuropathy improved gradually. The knee jerks reappeared in 16 days, while the ankle jerks could be elicited again after 3 weeks. Calf tenderness disappeared after 9 weeks of hospitalization and vibration sense returned at that time.

Comment. This was a case of upward nystagmus on forward gaze in an alcoholic individual. The vertical nystagmus was accompanied by vertical oscillopsia. Since the patient became aware of oscillopsia and since nystagmus and oscillopsia disappeared simultaneously, it may be safely assumed that these symptoms were acquired and not of the congenital type. The patient showed another rare disorder in eye movements: spontaneous zig-zag or dissociated eye movements, which are sometimes seen in subacute encephalitis and often associated with marked, almost myoclonic, tremors throughout the body. It is remarkable that amytal and even alcohol, when given intravenously, abolished the upward nystagmus on forward gaze. The spontaneous, dissociated, almost choreiform, eye movements were also abolished by amytal.   •

DISCUSSION

There are three points worthy of comment: (1) Nystagmus, (2) oscillopsia, and (3) effect of drugs on nystagmus and oscillopsia.

1. Nystagmus. Distinction must be made between vertical nystagmus on upward gaze and vertical nystagmus on direct forward gaze. Spontaneous vertical nystagmus on di-

rect forward gaze is seen almost solely in cases of congenital nystagmus. The spontaneous vertical nystagmus on forward gaze found in our two cases, however, is of the acquired type. In each, the oscillopsia appeared shortly before admission to the hospital and both the oscillopsia and nystagmus on direct forward gaze subsided concomitantly with treatment.

Both of the patients were chronic, severe alcoholics who exhibited signs of encephalopathy and peripheral neuropathy. It is known that such patients have diffuse lesions throughout the entire nervous system and that the brain stem is one region which is frequently involved in cases of severe alcoholism. One of the symptoms of disease of the brain stem is vertical nystagmus on upward gaze. Clinicopathologically, cases of vertical nystagmus on upward gaze have been reported in patients with verified lesions of the colliculi, of the caudal part of the pons and the medulla at the level of the inferior olivary bodies, and, in fact, with lesions of the brain stem at almost any level.[1]

There have been few, if any, reports of clinicopathologic studies of cases of vertical nystagmus on direct forward gaze. To date, therefore, it is not possible to localize the lesion in these cases of vertical nystagmus on direct forward gaze with any degree of accuracy. One can only suspect that the pathologic condition is somewhere in the brain stem.

On the other hand, judging from animal experiments, it would appear that the lesion might be in the vermis of the cerebellum. Lesions in the posterior part of the cerebellar vermis in the experimental animal have resulted in spontaneous vertical nystagmus.[5]

Using cats, Spiegel and Scala electrocauterized the vermis to obtain "positional nystagmus." They also recorded that the animal exhibited vertical nystagmus on being observed in its "normal position" which is analogous to forward gaze in the erect human subject.[5]

This vertical nystagmus in the normal

position of the operated cats consisted of very slow oscillations—five jerks in 30 seconds in one instance. The fast component was generally upward, but in one experiment in which both globose nuclei, the pyramis and uvula, were destroyed, it was downward.

2. *Oscillopsia.* Oscillopsia is a symptom caused by movements of the eyeballs. It is usually apparent in the vertical plane. Vertical oscillopsia has been reported in cases of multiple sclerosis,[6] encephalitis, brain tumors, and vascular disease of the brain and brain stem.

Oscillopsia can be produced by vestibular stimulation. Vertical oscillopsia is frequently found when vertical nystagmus is induced by the Bárány chair or caloric tests. However, when horizontal nystagmus is induced, it is interesting to note that individuals tend to report their sensations as "dizziness" and omit the phenomenon of horizontal oscillopsia.

Horizontal oscillopsia is often seen in cases of congenital latent nystagmus. It becomes apparent when there is interference with binocular vision. Thus, when one eye is covered or a piece of cardboard is placed on the bridge of the nose so as to interfere with binocular vision, a marked horizontal nystagmus becomes manifest. With this horizontal nystagmus, the patient complains that the observed object shimmers or moves back and forth in the horizontal plane.

3. *Effect of drugs.* Despite the presence of gross nystagmoid movements of the eyes, oscillopsia is not found in cases of congenital horizontal nystagmus on forward gaze. There is, instead, a marked impairment of visual acuity. Under the influence of intravenous sodium amytal, the ever present congenital nystagmus can be arrested. This is followed by an improvement in the visual acuity.[2]

As the effect of the amytal wears off and the congenital nystagmus reappears, the patient complains of foggy vision. Interestingly enough, there is no oscillopsia at this latter time but instead the visual images may appear elongated in the plane of the nystagmus, or may appear multiple.[7]

In our cases, intravenous sodium amytal or alcohol by mouth temporarily abolished both the acquired vertical nystagmus on direct forward gaze, and the concomitant vertical oscillopsia.

SUMMARY

Two cases of vertical nystagmus on direct forward gaze are described. Both of the patients complained of images bobbing up and down—vertical oscillopsia. When the nystagmus ultimately subsided the oscillopsia disappeared. Intravenous sodium amytal or alcohol temporarily abolished the vertical nystagmus and the concomitant vertical oscillopsia. Differentiation has been made between the acquired and the congenital types of vertical nystagmus on direct forward gaze.

TEMPORAL SUBCONJUNCTIVAL HEMORRHAGES AS A COMPLICATION OF RHINOPLASTIC PROCEDURES

WAYNE W. WONG, M.D.
Honolulu, Hawaii

AND

W. B. SLAUGHTER, M.D.
Chicago, Illinois

The occurrence of subconjunctival hemorrhages in one or both eyes as a minor complication of a rhinoplastic surgical operation is so consistent that this study was undertaken in an attempt possibly to explain some of the factors which cause these hemorrhages to be located in the temporal sector of the globe. It was thought that this study of 55 consecutive cases of rhinoplastic patients might also help to explain the frequent temporal location of the common spontaneous innocuous subconjunctival hemorrhages.

Only those cases that required a complete operation were selected. All operations were performed under local infiltrative anesthesia. The operating conditions and technique were essentially the same in the entire series.

In this series of 55 cases, subconjunctival hemorrhages were observed in 32 cases in one or both eyes. In 31 of these, the subconjunctival hemorrhages occurred only in the temporal sector of the bulb. Only in one patient were the hemorrhages other than temporal, this solitary case being circumlimbal in one of the eyes only. Even in this case, however, the hemorrhages were more intense in the temporal sector.

Table 1 shows the age, sex, degree of ecchymosis, and presence or absence of subconjunctival hemorrhages in these patients. The blood pressure was normal in all cases. No general systemic disease was found in the entire group. No local ocular inflammation was observed before, during, or after surgery. These cases were entirely elective and were done for corrective purposes.

From Table 1, it can be readily seen that the occurrence of subconjunctival hemorrhages is directly dependent on the degree of ecchymosis that is evident following surgery.

The degree of ecchymosis as listed in Table 1 was divided roughly into three groups. It was considered minimal when there was a slight puffiness of the lower lid with only a faint discoloration which disappeared in a few days; moderate, when both lids were swollen and discolored to a greater degree; and pronounced, when both lids were swollen shut and the discoloration of the lids was violescent (fig. 1).

When subconjunctival hemorrhages com-

plicate a rhinoplastic procedure, these factors are noted. Immediately postoperatively, the bulbar conjunctiva is not injected nor congested. There is no chemosis. The edema of the lids, in those cases that do have some reaction, is noted within 6 to 8 hours postoperatively. This is accompanied by a slight glassiness of the conjunctiva, with or without a slight congestion of the conjunctival vessels. This is due in part to the decreased sensitivity of the blinking reflex following the preoperative medication and the postoperative mental relaxation. No evidence of any subconjunctival hemorrhages is noted at this time.

TABLE 1

Occurrence of Subconjunctival Hemorrhages in Rhinoplastic Patients

No.	Sex	Age	Ecchymosis	Subcon-junctival Hemorrhages	Remarks
1	F	25	L.E. 3+	L.E.	Duration 3 weeks
2	F	18	B.E. minimal	None	
3	F	21	B.E. 2+	None	
4	F	27	B.E. 3+	B.E.	Duration 25 days
5	M	35	B.E. minimal	None	
6	F	18	Minimal	None	
7	M	18	B.E. 3+	B.E.	Duration 3½ weeks
8	F	21	R.E. 2+, L.E. 4+	L.E.	Duration 26 days
9	M	22	B.E. 4+	B.E.	Duration 4 weeks
10	F	26	B.E. 2+	L.E.	Punctate temporal
11	F	22	None	None	
12	F	23	Minimal	None	
13	F	23	R.E. 2+, L.E. 3+	B.E.	L.E. worse; duration 4 weeks
14	F	23	B.E. 3+	L.E.	Duration 20 days
15	F	15	B.E. 3+	B.E.	Duration 3 weeks
16	M	25	B.E. 3+	B.E.	Duration 3½ weeks

48	M	30	Minimal	None	
49	M	22	B.E. 2+	B.E.	Very small
50	F	24	B.E. 2+	B.E.	Small
51	F	18	Minimal	None	
52	F	28	Minimal	B.E.	Small
53	M	21	B.E. 2+	B.E.	
54	M	30	Minimal	None	
55	F	38	Minimal	None	

About 12 to 24 hours postoperatively, ecchymosis develops in one or both eyelids. The bulbar conjunctiva is not changed remarkably during this period. Immediate and constant use of ice compresses postoperatively does not appear to influence the de velopment nor the degree of ecchymosis in those cases that subsequently develop ecchymosis of the lids.

At the 24-hour postoperative period, sub

conjunctival hemorrhages have not yet appeared in all the cases that will eventually develop them. It is more common for the subconjunctival hemorrhages to appear between the 24th to 36th postoperative hour than between the 36th to the 48th hour. The general appearance of these subconjunctival hemorrhages when they first appear easily separates them into two distinct varieties.

In one group of patients, they form an intensely red triangular-shaped patch in the exposed temporal sector of the bulbar conjunctiva—the area delineated by the upper and lower lids as it meets the temporal limbus at about the 1:30 to the 4:15-o'clock positions. This area may or may not extend to the limbus, since there may be a bridge of clear conjunctiva between the limbus and the patch of hemorrhage. The hemorrhage may show some variation in intensity of color, but this is due mainly to the degree of oxygenation by the lacrimal secretion.[1]

On the second day of its appearance, there is a variable tendency for the hemorrhage to extend into the inferior fornix so that by the 72-hour period, the triangular patch may reach the limbus at the 6-o'clock position and may extend down into the inferior fornix, stopping at the inferior attachment of the palprebral conjunctiva. This downward extension is due to the massaging effect of the upper lid, as well as to gravity.

In a second group of patients, a less extensive type of hemorrhage is found. These occur as an irregular, horizontal, linear type of low-intensity hemorrhage and lie definitely in the 3- to 9-o'clock meridian. Composed of a small amount of blood, they are faint in comparison to the first type and their dense portion is usually closer to the limbus. The lateral extensions usually fade gradually into the normal surrounding conjunctiva. In width these hemorrhages are usually about 3 to 5 mm. at their widest portions. Such hemorrhages do not appear to be affected by the massaging effect of the lids nor by gravity.

The difference between these two types of hemorrhages is one of degree, although the causative factor and the location of the pathologic vessels are also different. In the first type, there appears to be a leakage from the deeper subconjunctival vessels; while in the second, there appears to be a diapedesis of the superficial conjunctival vessels. Ruedemann[2] describes these two types as (1) hemorrhages of obstruction and (2) hemorrhages of diapedesis.

The duration varies according to the amount of blood found subconjunctivally and the rate of absorption. Thus, some of these hemorrhages may be absorbed in 7 days while others may last as long as 4 weeks. The macroscopic rate of disappearance is unpredictable. A dense patch of subconjunctival hemorrhage may seem to remain stationary for many days but, in an equal number of days, the size of the hemorrhage may be rapidly reduced.

The direction of absorption is not always centripetal. In many cases, a clear patch of normal conjunctiva separates temporal patches of hemorrhage from the limbus, and this separation is maintained until the hemorrhages finally disappear. In other cases, the larger patches of hemorrhage are broken down into several smaller ones before they are finally absorbed. In most cases, however, the hemorrhage recedes slowly until there is only a small dot remaining at the 3-o'clock limbus. Massage does not appear to influence the rate of disappearance.

Studies[1] in the same patients of the resorption of subconjunctivally injected blood showed about the same rate of disappearance as spontaneously produced subconjunctival hemorrhages. However, these studies cannot be compared with the hemorrhages observed in our series since there were no disturbances of local circulation by adjacent surgical trauma.

Under the slitlamp one can readily see that the bulbar conjunctiva contains two layers of blood vessels.[2] The deeper layers of larger vessels are part of the branches of the anterior ciliary arteries and form a

part of the episcleral and scleral tissues. They anastomose rather freely with the superficial conjunctival vessels and penetrate the sclera about 3 to 4 mm. from the limbus. The superficial vessels are small and are located just beneath the conjunctival mucosa. There are approximately 2 to 3 times as many veins as arteries.

The difference in the size of the blood vessels between the deeper and superficial layers of conjunctival vessels forms the basis of the two types of hemorrhages. The large dense hemorrhage is from the deep vessels which are actually small arteries; whereas, the smaller, sketchy type of hemorrhage is from the superficial vessels which are arterioles and venules and are comparatively small. These hemorrhages are definitely venous in character. The greater number of veins in proportion to arteries in this region would leave the veins, according to the law of chance, more vulnerable to the forces of stress and strain.

If the superficial conjunctiva is touched with a moist cotton applicator or by the moving lids, it will move very freely over the deeper episcleral tissues. This freedom of movement appears to give the subconjunctival tissues an almost fluid appearance. It is in this rather loose areolar tissue that the subconjunctival hemorrhage occurs.

The dense type of hemorrhage, being from the deeper vessels, pours the blood from the bottom of this loose layer, therefore, making it impossible to locate the involved vessels. The thin sketchy type of hemorrhage empties the blood into this layer from the top of the areolar tissue. Here one can see small, faint patches of hemorrhage which appear as pinkish tufts located at the visible termination of the vascular tree. The confluence of these small areas of diapedesis produces a visible patch of subconjunctival hemorrhage.

The blood from the conjunctival vessels can be readily seen flowing toward the limbus in the normal conjunctiva. As these vessels are followed through an area of hemorrhage, their course stands out rather

clearly because there are clear areas paralleling them. The older the hemorrhage, the easier it is to see these perivascular channels, which are areas of absorption and digestion of the subconjunctival hemorrhage.

DISCUSSION

CIRCULATION OF CONJUNCTIVA

The circulation of the conjunctiva forms a part of the general circulation and is dependent on the general arterial pressure and on the general venous return flow. The arteries, capillaries, and veins, which form the circulatory units, are under the control of the vasomotor system that regulates the degree of constriction and dilatation of the vessels.

The local circulatory units can be subjected, therefore, to several kinds of disturbances.[3] (1) Vasomotor, which results from the change in neural control; (2) mechanical, such as those produced by mechanical obstruction of the lumen of the vessel either by a thrombus or an embolus within the lumen, by changes in the wall of the vessel, or by compression from without; and (3) biochemical, such as the action of split proteins from surgical trauma acting on the capillary wall or the action of surgical trauma depleting certain constituents from the body whose lack would in turn weaken the capillary wall.

The vasomotor disturbances have been shown by Ricker[4] to act in various degrees, depending on the strength of the stimuli. A weak stimuli affects the dilator fibers only and causes a dilatation of the vessels with an increase in the blood flow. A slightly stronger stimuli affects the constrictor fibers and causes a constriction of the arteries with a slowing of the circulation in the capillaries and veins. A stronger stimuli causes paralysis of the constrictor fibers and stimulation of the dilator fibers. At first this produces a dilatation of the vessels with an increase in the blood flow, but the dilator fibers soon become paralyzed and, above the dilated vessels, the artery is constricted. This results in

a slowing of the blood stream to complete cessation or stasis.

Depending on the action of the agents on the vasomotor system, three states of the local tissues can be distinguished. These are (1) active hyperemia with an increase in the blood flow, (2) passive hyperemia with a slowing of the blood flow, and (3) stasis or cessation of the blood flow.

Active hyperemia is produced by stimulation of the dilator fibers, the constrictor fibers remaining unaffected. Arteries, capillaries, and veins are dilated, and the blood flow is increased. There is, also, an enormous increase in the number of open capillaries with only a slight loss of fluid through the capillary wall.

Passive hyperemia with the slowing of blood flow occurs with the stimulation of the dilator fibers and a change in the constrictor fibers, which may either show a diminished activity or become completely inactive. In the region of the inactive constrictor fibers, the arteries, capillaries, and veins are dilated, and the circulation is slow and irregular. This form of hyperemia is characterized by an increased passage of fluid through the capillary walls and its accumulation in the surrounding tissues.

Stasis. When the central artery of the affected area becomes more constricted, there is still a greater dilatation of the vessels in the affected area and a still greater slowing of the blood stream results. Circulation is present but slowed. This form of vasomotor activity is characterized by the passage of red blood corpuscles through the capillary walls. They may pass through the capillary wall singly at one point, or hemorrhages may occur at a number of points. If the artery central to this area is markedly narrowed or completely occluded, the activity of the vasomotor fibers in the area is completely lost and, as a result, the vessels are relaxed and circulation is slowed to such a degree that stasis ensues. This latter state does not occur as a result of surgical trauma following rhinoplastic operations.

Obstruction to blood flow. The circulation of the conjunctiva can be disturbed mechanically by an obstruction to the flow of blood in the arteries or veins supplying it. When the obstruction is not complete and varying degrees of reflex constriction below the point of obstruction occur, there is a corresponding dilatation of the arterioles, capillaries, and venules distal to the point of constriction. The resulting condition produces a transudation of fluid and hemorrhages to a varying degree.

Mechanical obstruction of a vein is followed by a cessation of circulation in the vein and accompanied by a corresponding reflex constriction of the artery supplying the region. This occurs only in complete obstruction. Before circulation stops, however, there is first a slowing of the blood flow which produces a state of prestasis with its attendant hemorrhages. The immediate results of local circulatory disturbances are, therefore, a transudation of plasma into the tissues and attendant hemorrhages.

According to Landis,[5] the capillary blood pressure is capable of rising conspicuously during hyperemia (from 14 cm. of water to 23 cm. of water) and returns toward the lower resting level as hyperemia recedes. By the use of the micropipette introduced into the venous limb of a capillary at the base of the human fingernail, it was noted that, on cooling the skin at the base of the nail, a vasoconstriction resulted with a distinct drop in the capillary blood pressure. This, however, is followed in a few minutes by a secondary rise associated with a reactive hyperemia which has been studied so thoroughly by Lewis and his co-workers.[6] This mechanism may explain the nonbeneficial results of the ecchymosis reducing factor of ice compresses applied immediately postoperatively in our cases.

Another contributing factor in the production of these subconjunctival hemorrhages is suggested by an observation made by Hueck[7] that the protoplasm of the endothelial cells of the capillaries and the base-

ment membrane is capable of undergoing a transitory liquefaction to such a degree that it causes numerous openings to form and thus allows plasma and, in the case of larger openings, red blood corpuscles to pass through. This condition is produced in the state of prestasis, when the slowing of the circulation in the capillaries causes a diminution in the supply of oxygen and of nutrition to the walls of the capillaries. This same observation was also noted by Landis[5] in the capillary of the frog.

PHYSIOLOGY OF CAPILLARIES

Most of the studies on the physiology of the capillaries have been made on the vessels themselves with little regard of the action of the contents of the vessels. The observations of Knisely and his co-workers[8] on the action of traumatized capillaries on the blood corpuscles and their subsequent effect on the capillaries themselves throw new light on the basic pathologic physiology of the blood vessels.

Briefly stated, Knisely discovered that, in injured tissue and blood vessels and in certain diseased states, the individual blood corpuscles become agglutinated and form clumps of cells. This mass of cells or "sludge" resists its own passage through the small vessels and consequently the rate of flow in these vessels becomes progressively slower. The "sludge initiating factor" at the site of injury continues to form more "sludge blood" which reduces the rate of flow through the capillary bed and slowly leads to various degrees of stagnant anoxia all over the body.

When this happens the walls of the postcapillary venules and small venules lose their ability to retain blood colloids. Anoxia of the endothelium is alone sufficient to cause this and severe anoxia always causes endothelium to leak rapidly.

One of the key facts in Knisely's observation is that blood coming through the arterioles of any organ may be studied as a valid sample of all flowing arterial blood in the body. He has used the uninjured bulbar conjunctiva of human beings in the study of "sludge blood" in various diseases.

It appears that one of the important factors in the production of subconjunctival hemorrhages is a local weakening of the capillary wall to any increase in intravascular pressure. The strength of the capillary wall is actually a measure of the intracellular adhesive power of the endothelial cells which make up the capillary wall.

This is, in turn, affected by such substances as rutin, vitamin P, citrin, and so forth, which are flavone glucosides in various degrees of purification, and factors causing endothelial anoxia. There is some question as to the mode of action of these substances and as to whether the tourniquet test which measures capillary fragility has any bearing on capillary hemorrhages.[9]

Wolffe and Danish[10] reported two cases in which subconjunctival hemorrhages occurred during the administration of rutin. In one case, the hemorrhage occurred about four weeks after continuous rutin therapy. In the second case, the hemorrhage occurred 24 hours after the starting of rutin therapy. In both of these cases capillary fragility tests, as measured by the Gothlin method, were normal.

The possibility that other causes may be concerned in the integrity of the normal cells must also be considered.[11, 12] It is highly improbable that the explanation can be found in a single agent or a group of similar agents but rather in a complex biologic reaction of which the flavone glucosides form only a part.

STRUCTURE OF TEMPORAL CONJUNCTIVA

The almost constant location of these subconjunctival hemorrhages in the temporal sector of the bulb can be explained on an anatomic and functional basis. It is a well-known surgical fact that the structure of the temporal conjunctiva is much thinner than that of the nasal sector. The ocular movement of convergence, being a positive

function, places a stretching force on the conjunctiva of the temporal sector while that of the nasal sector is compressed into folds.

In addition, the anterior ciliary arteries that travel around the eyeball on the recti muscles are usually paired on all the recti muscles, except for the lateral rectus which usually carries one and occasionally no visible artery.[13, 14] The stretching force of ocular convergence on the temporal conjunctiva plus the strain of any venous obstruction would weaken this sector more than the others.

Biochemic Effects of Trauma

The biochemic effects of trauma have been studied in severe injuries, such as burns and fractures.[15] It seems probable that the formation of "sludge blood" is directly or indirectly concerned with the biochemic effects of trauma. Andreae and Browne[15] observed a rapid and marked destruction or utilization of ascorbic acid during the period immediately following injury.

Levenson and others[16] state that the stresses associated with severe injury are followed by a markedly increased turnover of protein and carbohydrate metabolism. Since it is known that the vitamins of the B group are intimately concerned with the metabolism of these substances, it is likely that the demand for and the utilization of them is likewise increased.

However, the trauma associated with the surgical procedure of rhinoplasty cannot be compared with cases of severe injury whose measurable demands on the body physiology are definite. Nevertheless, one may expect some of the physiologic forces to come into play, even though to a much lesser degree, in less severe injuries.

With all these factors contributing to the development of the temporally located subconjunctival hemorrhages in postrhinoplastic cases, it appears that the variable factor is the patient's reaction quotient to trauma. This particular aspect of the problem has been studied in the lower animals.[17, 18] The degree of postoperative edema in our cases would be a rough measure of the individual patient's reaction to trauma. When we consider this variable individual factor, the formation of these subconjunctival hemorrhages is the end result of a multitude of physiologic conditions.

Synopsis

The chain of events may be hypothesized in the following manner. The operative trauma causes an increase in the protein concentration of the lymph.[19] The formation of "sludge blood" now becomes a factor. This increase in protein concentration may not, in itself, change the permeability of the capillary walls[20] but, with a given capillary pressure, the colloidal osmotic pressure may vary to such an extent so as to influence capillary permeability.[5] Whether the permeability of the capillaries is changed reflexly or by the slowing of the blood stream by sludging, the total tissue anoxia and subsequent edema are increased. This postoperative edema causes a congestion of the angular veins and of the internal pterygoid plexuses so that the drainage from the external eye is affected directly and, possibly, reflexly.

The operative trauma may further deplete or utilize more rapidly certain substances which may have to do with capillary fragility. The subconjunctival hemorrhage is, therefore, a result of a disturbance in venous circulation when the postoperative congestion exceeds the intracellular adhesive power of the capillary wall. This congestion requires about 24 to 48 hours to create enough obstruction so that any sudden further increase in venous pressure, such as might be caused by coughing, laughing, or straining, plus the factor of ocular convergence, would be enough to put a strain on the weakest spot of the conjunctival vascular tree.

The single lateral rectus ciliary artery would have to carry a pressure load which in the other recti muscles is divided between two vessels. Moreover, the rare occurrence

of a spontaneous subconjunctival hemorrhage over the superior or inferior recti muscles is partly due to the compression and support afforded these areas by the upper and lower lids. The nasal and temporal 'sectors are subjected to an increase in the local vascular pressure. The structural weakness of the temporal conjunctival vascular tree is thus made evident by the typical temporally located subconjunctival hemorrhage.

Trauma per se is definitely not related to these hemorrhages. In a case in which a 12-mm. dermoid cyst was excised from the left supraorbital region under local infiltration anesthesia, a very large temporal patch of subconjunctival hemorrhage was noted within 24 hours postoperatively. There was a moderate amount of edema of the upper lid in this case, but the trauma incident to the removal of the cyst was certainly minimal.

In Case 43, in which it was necessary to fracture only one maxillary process, the subconjunctival hemorrhage occurred in the temporal sector of the opposite eye. The factor of a contrecoup force must be considered in this case, but it does not account for the absence of subconjunctival hemorrhages in those cases in which the apparent hardiness of the maxillary process required an excessive amount of trauma and yet no hemorrhages appeared. These observations seem to suggest that trauma in itself is not a sufficient cause but rather that the response of these patients to surgical trauma is the important factor.

SUMMARY

1. In a series of 55 consecutive cases of rhinoplastic patients, 32 cases, or 58 percent, developed temporally located subconjunctival hemorrhages as a complication of the surgical procedure.

2. These subconjunctival hemorrhages were of two varieties, an intensely red triangular type and a streaky horizontally linear type.

3. Both of these types of hemorrhage appeared to be definitely related to the degree of postoperative ecchymosis and not to the degree of surgical trauma.

4. These hemorrhages always appeared from 24 to 36 hours following surgical trauma.

5. They were definitely venous in nature.

6. A discussion of the possible mode of formation and an explanation of their temporal location has been given.

OPHTHALMIC MINIATURE

To Mrs. Jane Mecom

London, July 17, 1771

Dear Sister,

. . . I thought you had mentioned in one of your letters a desire to have spectacles of some sort sent you; but I cannot now find such a letter. However I send you a pair of every size of glasses from 1 to 13. To suit yourself, take out a pair at a time, and hold one of the glasses first against one eye, and then against the other, looking on some small print.—If the first suits neither eye, put them up again before you open a second. Thus you will keep them from mixing. By trying and comparing at your leisure, you may find those that are best for you, which you cannot well do in a shop, where for want of time and care, people often take such as strain their eyes and hurt them. I advise your trying each of your eyes separately, because few peoples eyes are fellows, and almost every body in reading or working uses one eye principally, the other being dimmer or perhaps fitter for distant objects; and thence it happens that the spectacles whose glasses are fellows suit sometimes that eye which before was not used tho' they do not suit the other.— When you have suited your self, keep the higher numbers for future use as your eyes may grow older; and oblige your friends with the others. . . .

Your affectionate brother,

B. FRANKLIN.

NOTES, CASES, INSTRUMENTS

CILIA IN THE ANTERIOR CHAMBER*

WITH A REPORT OF A CASE

OLGA SITCHEVSKA, M.D., AND
BRITTAIN F. PAYNE, M.D.
New York

Cilia may enter the anterior chamber in perforating injuries of the eyeball, when they are cut or torn off from the lid margin and are carried into the anterior chamber either through the corneal or limbal wound. Occasionally the cilia may be implanted into the anterior chamber during surgical intervention for a cataract extraction.

The cilia sometimes are found lying free in the anterior chamber, but more frequently one end of the cilium is embedded in the iris. If the lens is injured one end of the cilium is stuck in the lens or lens capsule. In some cases the cilium is adherent to the corneal scar. Cilia are observed less frequently in the posterior chamber.

If cilia remain in the anterior chamber for a length of time, they may undergo certain changes, like splitting of the hair or separation of the cuticle. Blanching or depigmentation of the cilia may occur under the influence of the alkaline reaction of the aqueous. Wagenmann[1] stated that cilia may be occasionally absorbed by giant-cell formation.

Considering the frequency of perforating eye injuries, it is remarkable that cilia are not found more often in the anterior chamber. Sherman[2] gives an interesting explanation of this phenomenon. He believes that the reflex closure of the lid is usually delayed until the injury of the eyeball has occurred, so that the traumatizing object misses the contact with the lid margin. On rare occasions the closure of the lids occurs simultaneously with the impact of the injuring object which cuts the cilia and carries them into the anterior chamber. The injuring object in such cases frequently does not enter the eyeball as its force of motion is diminished by its friction against the lid margin.

FREQUENCY OF INFECTION

Since cilia usually enter the eye in industrial accidents, in workers whose faces and eyelashes are soiled during the work, one could expect that the eyelashes would be a source of infection. This, however, does not occur frequently. It would seem that the rapid filtration of the aqueous from the anterior chamber allows little opportunity for bacterial growth there.

Lauber[3] believes that when an infection occurs in perforating injuries, it may have been brought about by the perforating object rather than by the cilia themselves. Müller[4] in culturing cilia of a number of working persons found no pathogenic microörganisms.

On the other hand, in a case described by Wagenmann[1] a cilium implanted in the anterior chamber caused a purulent iritis with a hypopyon 2.5 mm. high. After the removal of the cilium, the inflammation subsided promptly. Sympathetic inflammation was observed by Gunier[5] six months and by von Graefe[6] two weeks after the perforating injury with cilia implantation had occurred. Extraction of the cilia resulted in healing of the eyes.

COMPLICATIONS FROM RETAINED CILIA

While cilia may remain in the anterior chamber for a long time without giving rise to disturbing symptoms, they may sooner or later cause complications, such as epithelial tumors. The epithelium of the root sheath may become implanted, forming a cyst.

---

* From the New York Eye and Ear Infirmary.

"The implantation cysts thus formed may be of two distinctive types: solid looking, round or oval tumors, so-called pearl cysts, or translucent cysts with thin walls" (Duke Elder[7]).

Implantation cysts of the iris associated with the intrusion of an eyelash into the interior of the eye were reported by Bonnet and Paufique,[8] and Roth and Geiger[9] in whose case the injury was caused by a lead pencil, by Krachmalnikov,[10] Moore,[11] and by Horay.[12]

CILIA IN ANTERIOR CHAMBER

Cilia in the anterior chamber are not common. Popov[13] states that only two such cases have been seen among 80,000 eye patients in the Rostov Clinic and only one case in three years was found among 43,471 patients in the Astrakhan Clinic. Müller[4] reported that only five cases of cilia were observed in Fuchs's clinic in Vienna among 30,000 new patients. Sharpe[14] in his review of the literature, in 1925, stated that 75 similar cases were reported within the last 100 years.

At the New York Eye and Ear Infirmary, out of a total number of 374,721 eye patients examined during 15 years (1932 to 1947), only two such cases (including ours) have been recorded. These data confirm the infrequency of penetration of cilia into the interior of the eye.

Reports in the literature indicate that cilia may remain in the anterior chamber for a number of years without causing inflammation. Gradle[15] examined a 24-year-old man for blepharoconjunctivitis. There was a history of an injury to the right eye with scissors at the age of five years. The slit-lamp examination showed the presence of a depigmented cilium in the anterior chamber. The cilium has been there for 19 years without evidence of inflammation.

Hughes,[16] while refracting a naval officer, discovered an eyelash in the anterior chamber. A history was obtained from the patient that he was injured in the eye with a fountain pen when he was a child.

Roll[17] reported a case of a cilium being adherent to the opaque lens for a period of 19 years. Koenigstein[18] and Guzman[19] observed a cilium in the anterior chamber for 20 years. Henneberg[20] reported that inflammatory symptoms appeared 15 years after a perforating injury of an eye with the implantation of a cilium. Sharpe[14] reported a case of a cilium in the anterior chamber for 33 years. Schwartz[21] and Müller[4] each described a case of eyelash in the anterior chamber for 34 years. The eyes remained quiet all that time.

CASES OF MORE THAN ONE CILIUM

It is evident from literature that cases of cilia in the anterior chamber are rare, and cases in which more than one cilium is observed are still rarer. Shagov[22] discovered two cilia in the anterior chamber after a magnet extraction of a piece of steel from the eye. An attempt to remove the cilia was unsuccessful as they moved to the posterior chamber. They remained there for a two-year period of observation.

Lichtner[23] and Payne[24] removed two cilia from the anterior chamber after a perforating injury of the eye. Franklin and Cordes[25] found three cilia and Sharpe[14] and Begle[26] have observed four eyelashes in the anterior chamber.

Bulson[27] and Valude[28] each reported a case of five cilia entering the interior of the eyeball after a perforating injury with a piece of wire. Mikhailov[29] reported a case of six cilia in a young woman's eye which was hit with a piece of wood; they were embedded in the iris. Three cilia were removed with an iris forceps with ease through an incision at the limbus, while the other three were removed with great difficulty and a cataract formed a week later.

REMOVAL OF CILIA

The removal of the cilia from the anterior chamber is by no means a simple procedure, particularly when more than one

cilium is implanted. A number of complications may occur: the collapse of the anterior chamber because of the rapid outflow of the aqueous, the tendency of the iris to prolapse, or a hemorrhage from the iris which obscures the operating field. The most serious danger is the injury to the lens. Paderstein[30] reported a case in which he

in the left eye by a fine piece of wire from another toy a nearby worker was handling. She experienced a sharp pain in the eye and the vision became blurred at once.

Eye examination. There was marked photophobia and ciliary injection of the left eyeball and a gaping wound of the cornea at the 12-o'clock position, 4 mm. below the
Fig. 1 (Sitchevska and Payne). Photograph of slitlamp drawing of two cilia implanted in the anterior chamber following a perforating injury of the left eye. The cilia, embedded in the iris, are enveloped by an exudate.

removed a cilium 5 weeks after a penetrating wound of the eyeball; 8 weeks later another cilium was seen and the attempt to remove it was frustrated by a hemorrhage from the iris with the lens becoming cataractous a week following the operation.

REPORT OF A CASE

History. - E. J., a Negro girl, aged 19 years, was first seen on March 4, 1948, one-half hour after an injury to the left eye. While working on a toy, she was struck

limbus. The anterior chamber was filled with clotted blood, mixed with grayish shreads of the turbid aqueous; the fundus could not be seen. Vision was reduced to hand movements. The right eye was normal and the visual acuity was 20/15.

The patient was hospitalized at the New York Eye and Ear Infirmary. She was given cold compresses, drops of a solution of atropine sulphate, and intravenous injections of triple typhoid vaccine. Three days later the hyphemia was absorbed.

The slitlamp examination showed that the corneal wound was sealed and the anterior chamber was restored. The aqueous was still somewhat cloudy. A square corneal opacity was forming at the site of the injury and there was another deep-seated opacity in the cornea at the 6-o'clock position, 3 to 4 mm. above the limbus, which extended toward the temporal side of the cornea.

The striking feature of the slitlamp examination was the presence of two thin, long foreign bodies in the anterior chamber which were recognized by one of us (B. F. P.) as cilia. The cilia were embedded in the pupillary margin of the iris at the 7-o'clock position. One cilium was located at the anterior border of the iris; while the second seemed to be behind in the posterior chamber. They were surrounded with a newly formed grayish exudate.

The free ends of the cilia were extending obliquely across the dilated pupil at about axis 70°. A small opacity in the lens capsule near the embedded cilia was observed. A posterior synechia had formed, and the pupil was of irregular shape at this site (fig. 1).

The roentgenogram showed no intraocular foreign body. The eye quieted down; vision improved to 20/50; and the patient was discharged from the hospital three weeks after admission.

Course. Four weeks following the injury, the patient complained of pain in the eye. Photophobia and ciliary injection were present and a flare in the anterior chamber was observed on slitlamp examination. She was re-admitted to the hospital and was operated on April 6, 1948 (5 weeks after injury), under local anesthesia for the removal of the cilia.

Operation. A keratome incision was made at the 9-o'clock position at the limbus and the incision was enlarged with scissors on either side. A Hunt capsular forceps was used to enter the anterior chamber, and one cilium was removed with ease. It was dif-

ficult to remove the second cilium, however, and several attempts were made before it was finally grasped and removed. A small peripheral iridectomy was done in order to prevent prolapse of the iris.

At the conclusion of the operation a pigmented, filmlike emulsion filled the anterior chamber, which had to be irrigated. This probably was free pigment from the pigment layer of the iris. Postoperatively, the patient was put on intramuscular injections of penicillin. Recovery was uneventful.

At examination, five months after the injury, the eye was quiet, an opacity of the cornea was seen below the limbus at the site of the entrance wound and another one was present at the 9-o'clock position, the field of the operation. A third pigmented corneal opacity was deeply seated about 4 mm. above the limbus at the 5-o'clock position. The opacity of the lens capsule remained unchanged. The vision of the eye was 20/50, unimproved.

CONCLUSION

A case of two cilia in the anterior chamber following a perforating injury of the eye and their successful removal is described. The fine piece of wire must have hit the eye and lid with sufficient force to cut off the cilia and carry them into the anterior chamber, injuring the cornea below from the endothelial side and causing no injury to the lens itself, which is rather remarkable in a penetrating injury of this type.

The frequency of occurrence, the number of eyelashes in the interior of the eye, complications encountered during the operation for their removal are discussed.

Although the cilia may be retained for a number of years in the anterior chamber without giving rise to symptoms, it is our belief that an attempt should always be made at the earliest possible moment to remove them because of various threatening complications, chiefly that of the formation of epithelial cysts.

POSTOPERATIVE WOUND INFECTION CURED BY PENICILLIN*

BEULAH CUSHMAN, M.D.
Chicago, Illinois

History. Mr. H. J. H., aged 38 years, came to the late Dr. G. F. Suker in September, 1931, with the history of attacks of blurred vision in the right eye, lasting for 10 minutes to one hour, for three years. Vision in the left eye had become blurred for the first time a few days earlier.

A diagnosis of chronic glaucoma was made, and deep root iridectomies were done on both eyes in October, 1931. Miotics were necessary in the right eye after a few weeks and in the left eye after a few months.

Tension in the right eye gradually increased and remained around 35 mm. Hg (Schiøtz), with a total loss of vision in 1937. The tension in the left eye was irregular at intervals, but it always responded satisfactorily to the use of various miotics. Prostigmin solution and tablets by mouth were found to be the most satisfactory treatment when the patient became sensitive to pilocarpine after 1940.

Course. In 1944, the refraction gradually changed to a compound myopic astigmatism and there was a mild iridocyclitis of the right eye. An incipient cataract was present in the left eye. In April, 1946, the diagnosis of diabetes mellitus was made. This condition was controlled with diet.

Operation. On August 14, 1946, Dr. Der-

Fig. 1 (Cushman). Visual field studies before and after cyclodialysis and intracapsular lens extraction in the left eye.

rick Vail did a cyclodialysis of the left eye preliminary to an intracapsular lens extraction in this eye. The lens extraction was done the following week.

On the day following the operation, pain was complained of during the early morning, but no pain was present at the time of rounds, and the dressing was not changed. On August 16th, when the dressing was changed, an exudate was present along the corneal wound and in the anterior chamber. The conjunctiva was swollen and the upper lid edematous. Scattered, superficial abscesses were present in the skin of the upper lid.

Infection and treatment. A smear was positive for Staphylococcus hemolyticus, and later the culture was reported positive. Penicillin (1,000 units) was dropped into the eye immediately, and 10,000 units were given intravenously every three hours. Typhoid vaccine (15,000,000) was given.

The following day, penicillin was instilled into the anterior chamber after removal of 0.1 cc. of aqueous by means of a fine needle introduced through the recent incision. Sulfadiazine and soda bicarbonate (10 gr. every 4 hours) were given.

Improvement of the eye was immediate following the instillation of penicillin into the anterior chamber, and healing proceeded most satisfactorily.

Outcome. Vision in the left eye was: October 21, 1946—fingers at three feet; left pupil drawn up; April 14, 1947—iridotomy; June 24, 1947—20/16 with a +11.0D. sph. +4.0D. cyl. ax. 160°; with a +4.0D. addition, 4-point type.

The visual field of the left eye was contracted to 20 degrees with a 3/1,000 test object. There was complete cupping of the left disc. Tension in the left eye was 19 mm. Hg (Schiøtz).

25 East Washington Street (2).

SOME OCULAR EFFECTS OF THE SYSTEMIC ADMINISTRATION OF ANTIHISTAMINICS

Joseph V. M. Ross, M.D.
Berwick, Pennsylvania

The use of antihistaminics is becoming an increasingly popular procedure in everyday medicine and a rather complete knowledge of the side-effects of such drugs seems to be desired. Ocular side-effects have been recorded often in the literature and in a review of 12 articles[1-12] I found them men-

tioned in 6. Some of the authors feel that most antihistaminics possess an atropinelike or vagal-paralyzant effect. There seems to be some disagreement as to whether or not oral administration might give pupillary dilatation and reduce the capacity for accommodation as does topical application. Blurred or dim vision is the ocular complaint mentioned. In one report in which a shocklike effect followed the oral administration of an antihistaminic, it was not clear if the origin of the blurred vision was cerebral or not.

During the past two years I have seen four cases in which the use of an antihistaminic resulted in ocular complaints, and which bring up some problems that warrant reporting.

CASE REPORTS

Case 1. A. G., a woman, aged 38 years, was receiving therapy for a limbal type of vernal conjunctivitis. Before medication was given, vision was normal for near and far with or without the correction (determined by cycloplegia): O.D., +0.5D. sph. $\bigcirc$ −0.5D. cyl. ax. 175°; O.S., +0.25D. sph. $\bigcirc$ −0.25D. cyl. ax. 170°. The patient received 100 mg. pyribenzamine daily for 13 days, at the end of which time she complained of blurred vision for far and near with difficulty in reading. Vision was 20/30, O.U., at far and 8-point type was read at 14 inches, O.U. Refraction revealed the following: O.D., +0.25D. sph. $\bigcirc$ −1.0D. cyl. ax. 175° = 20/20; O.S., −1.5D. cyl. ax. 170° = 20/20. An addition of +1.5D. sph., O.U., was necessary to give normal near vision.

With a contact lens in place, the following was found: O.D., +0.25D. sph. $\bigcirc$ −0.5D. cyl. ax. 175°; O.S., −1.0D. cyl. ax. 170°.

The amplitude and range of accommodation were diminished and the refractive changes noted, but all other ocular findings were normal. With cessation of the medication all symptoms disappeared and the findings at a later date were the same as at the early visits.

Case 2. J. M., a man, aged 65 years, had relative visual acuity of 20/50, O.U., and 0 at 14 inches, O.U., corrected to normal at near and far. The patient had chronic asthma and, after having taken 100 mg. of pyribenzamine daily for one month, complained of blurred vision for near and far.

Ophthalmic survey was normal except for vision of 20/40, O.U., at 6 meters with corresponding near vision, not correctible. There was a diffuse corneal edema similar to that seen following the ingestion of atabrine and an increased corneal relucency. The refraction (which was done with difficulty) was the same as found previously. All symptoms cleared when the drug was stopped; all findings were normal in one week.

Case 3. W. F., a man, aged 55 years, presented a bilateral contact dermatitis of the lids. Both near and far vision were easily corrected to normal. Eight days after taking 75 mg. of pyribenzamine daily he complained of blurred vision, especially for near. The patient saw 20/20 O.U., however, but only read 8-point type at 14 inches instead of 4-point, but with a +3.25D. addition, O.U., instead of the +2.25D. he was wearing, read normally at near.

All other findings were normal except for the finding of a few vitreous opacities which were not noted previously. Refraction for distance was the same as previously. In one week after cessation of the drug, the patient had no complaints and the findings were as they had been at the first visits. The vitreous opacities persisted, however, and the patient was now conscious of them.

Case 4. G. H., a boy, aged 11 years, presented a limbal type of vernal conjunctivitis for which pyribenzamine was given (100 mg.) for two days. Relative visual acuity was 20/25, O.U. Cycloplegic refraction then revealed the following: O.D., +0.5D. sph. $\bigcirc$ −2.75D. cyl. ax. 7° = 20/20; O.S., +0.5D. sph. $\bigcirc$ −2.5D. cyl. ax. 175° = 20/20. The postcycloplegic findings two weeks later were the same, but the patient

complained of a mist before the eyes. Now, only 20/25, O.U., vision could be attained. The pyribenzamine was discontinued and two weeks later the refraction with cycloplegia was: O.D., +0.25D. sph. $\subset$ −0.5D. cyl. ax. 18° = 20/20; O.S., +0.5D. sph. $\subset$ −0.5D. cyl. ax. 172° = 20/20. All other findings were normal throughout.

SUMMARY

Four cases are presented in which there were ocular side-effects from the systemic administration of antihistaminics. The condition for which the drug was originally administered was not benefited in any case. The complaint in all these cases was blurred vision for far and near. The mechanisms involved were varied and all the reasons are not clear at this writing. In no case were the pupillary reflexes disturbed.

In Case 1, there was a depression of accommodation as well as refractive changes. Use of the contact lens suggested that these changes were due, at least in part, to factors other than corneal. The refractive changes were similar to those in Case 4.

In Case 2, that of a patient who had been asthmatic for years, there was seen a diffuse corneal edema with an increase in corneal relucency and no other significant changes.

In Case 3, a depression of accommodation only was noted. The question of the vitreous opacities is not settled.

In Case 4, an extreme refractive change occurred and the patient needed high minus cylinders at an axis of nearly 180°.

All changes abated with discontinuance of the drug, and the drug was not readministered to test specificity of action. The exact incidence of ocular side-effects was not determined.

DISCUSSION

The ophthalmologist should certainly include in his history a question as to whether the patient is taking antihistaminics. In some cases, these drugs can cause blurred vision for near and far. The factors as determined in these cases were corneal edema, refractive changes, and depression of accommodation. Apparently factors other than corneal are involved in the refractive changes although corneal changes might likewise occur. The depression of accommodation might well be explained by the atropinelike action of the drug. The presence of vitreous opacities in one case brings up the possibility of vitreous changes.

A NEW ORBITAL IMPLANT

ORWYN H. ELLIS, M.D.
Los Angeles, California

Many new orbital implants for use following enucleation have been developed during and since World War II and much of the credit for stimulating interest in this work must go to Cutler.[1,2] A new type of completely covered implant, which embodies a combination of sound surgical and prosthetic principles, is presented in this report. The indications for enucleation and evisceration will not be discussed, and only minor points in the enucleation procedure, as they affect the orbital implant, will be presented.

SURGICAL ANATOMY

As is well known, Tenon's capsule and the conjunctiva are fused with the sclera for a distance of 1 to 2 mm. about the limbus. The normal cornea has an average diameter of between 11 and 12 mm. Thus in doing an enucleation, approximately 16 mm. of circumference are lost.

The exact size of a sphere which can be inserted into the reduced space of Tenon following an enucleation can therefore be computed by subtracting the lost circumference from the circumference of the eyeball. In an adult a round implant of more than 18 mm. in diameter will stretch Tenon's capsule, and I agree with Fralich[3] that those surgeons recommending an implant of 20 to 21 mm. in diameter are forgetting the size of Tenon's space after enucleation.

When Cutler basket implants were used, I found that they were frequently extruded and that, when retained, considerable atrophy developed above and behind the implants. It was also noted, especially in children, that the conjunctiva pulled into the

cavity was at the expense of the conjunctiva of the cul-de-sacs, especially the superior. A prosthesis that could be inserted had, therefore, to be narrow with very little motion. It is a well-established fact that the prosthesis will move in direct proportion to the movement of the cul-de-sacs, provided transfer of motion from the implant stump to the prosthesis is successful. If atrophy or reduction in size of the cul-de-sacs takes place, motion of the prosthesis is correspondingly reduced.

NEW IMPLANT

When Cutler's basket implants were placed in orbits, I noted that the prosthesis made after the socket-mold technique moved about the same whether or not the peg or stud was added to the prosthesis. A plastic basket was then made increasing the depth with plastic, with the idea that the muscles could be attached to the rim or tied through the holes and that the rim and sides of the implant would transfer motion to the prosthesis.

Later it was found that, by increasing the amount of plastic posteriorly so that the implant was essentially a plastic sphere with a rim, the prosthesis could be fitted to the sides where the covered implant transfers motion most readily to the prosthesis (fig. 1) and that, by so doing, motion could be increased.

PROCEDURE

The procedure of choice as it evolved is: The conjunctiva is incised as close to the limbus as possible. The conjunctiva and Tenon's capsule are then freed from the globe by blunt dissection. One rectus muscle is isolated and Tenon's capsule is stripped well back. A double-armed chromic catgut

suture is placed in the tendon, adding a cinch suture in the lateral band of the tendon, similar to the muscle stitch of Wiener.[4] The tendon is then cut from the globe. In succession the tendons of the other three recti muscles are similarly sutured and cut. The enucleation is completed and the hemorrhage controlled.

Next, the ends of each suture are passed through the corresponding holes under the rim of the implant and the tendons are tied together, medial to lateral and superior to inferior. If desired, the tendons may be attached to the rim in the manner described by Cutler.[2] However, to date and in my hands, Cutler's technique has seemed to prolong the procedure unnecessarily.

A running purse-string suture of white silk is then placed in Tenon's capsule and pulled tight, completely covering the implant. It was found that Tenon's capsule must be separated well back from each muscle before cutting it loose from the globe, otherwise the operator will be unable to close the capsule completely over the implant. A simple running black silk, or interrupted sutures, are used to close the conjunctiva in a horizontal line.

When the optic nerve is cut, a perforation of the capsule is made posteriorly through which an implant could be forced if one too large were inserted. Irvine[5] recommends suturing this posterior hole. He finds that this gives good support, since it brings the implant well forward. However, this method results in a considerable reduction in the size of the remaining Tenon's space, and it is therefore necessary to use an implant of smaller size.

Postoperatively, with the new implant, there has been surprisingly little edema, no more than with the routine enucleation using a glass-ball implant without muscle sutures. The original pressure dressing should be left in place 5 to 7 days, if possible. By this means postoperative edema is kept to a minimum. In no case has the conjunctiva bulged out between the lids. These patients are usually ready for a temporary prosthesis before two weeks.

DISCUSSION

When a glass-ball implant was used, the implant stump usually moved well in all directions, but the stump did not transfer its
Fig. 1 (Ellis). A new orbital implant. (A) Side view. (B) Top view.

motion to the prosthesis. With this new implant, the movement of the ring is transferred directly to the prosthesis, and the lag of motion frequently seen in covered implants has not been noted.

The implant is made in varying sizes. In most adult orbits the large (18 mm.) size fills Tenon's space nicely but does not distend it. The implant is of the proper depth so that the covered rim protrudes 2 to 4 mm. which is adequate to provide flat sides for the proper fitting of the prosthesis. The inner surface of the prosthesis is molded to fit as snugly as possible around the outside of the projecting rim and sides of the implant. In this manner it is possible to avoid pressure on the conjunctiva, the weight is distributed evenly and, since the prosthesis does not rest on the lower lid, sagging is eliminated. After the prosthesis is fitted a wide excursion is present, but movements in the extremes of rotation are not necessary.

The status of implants that are not completely covered with conjunctiva has not been fully settled. A number, even under the most favorable conditions, are not re-

tained. Frequently, the muscles pull loose from the implant. When the implant herein reported is used, the muscles are attached with ease, and they aid in maintaining the implant in its proper position in the orbit.

Sensitivity to acrylic has occurred following use of implants not completely covered by conjunctiva. In some instances, apparently, a foreign-body reaction has taken place. No case of sensitivity to this new implant has come to my attention. The fact that it has been made only from Lucite may account for the lack of reaction.

To date a total of about 80 of these implants have been used by a number of ophthalmologists besides me, all of whom are enthusiastic about the ease of insertion, the normal appearance of the prosthesis, and the extensive excursion usually present when this implant has been used in conjunction with a prosthesis expertly made by the socket-mold technique. In only one case has there been extrusion or migration of the implant. A number have now been in place for two years. In no case has the implant changed position, orbital atrophy has not occurred as yet, and complications concerning the prosthesis have been few and of minor importance.

Since the introduction of this implant, quite a number of modifications have appeared. In some instances, the rim has been omitted; in others, the rim has been flattened. These changes, in my opinion, are steps backward. The Cutler basket implant taught us one thing—that the rim will transfer movement from the implant to the stump which, except in rare instances, the round implant will fail to do. The implant herein presented is certainly not perfect. It is in a stage of development from which, it is hoped, an implant that will satisfy all specifications may be evolved.

When the procedure as presented is used with the new implant, uniformly good results will be obtained. The method is not technically difficult and requires little additional time to that of routine enucleation with implant. One of the most important factors in orbital implants is permanency, and to date the completely covered implant herein described gives every promise of fulfilling this requirement.

HISTORICAL MINIATURE

Egyptian Ophthalmology

The "rising of water in the eye" was treated with a preparation of lapis lazuli, verdigris, balsam, milk, and crocodile earth. Ebers interprets the name of the disease as cataract, but Hirschberg agrees with Lüring that intractable epiphora is meant.

Dr. Jerome A. Sansoucy, *president*

ABNORMALITIES OF THE OPTIC DISC

Dr. Frank B. Walsh, Baltimore, Maryland (by invitation) spoke on "Abnormalities of the optic disc; their importance in diagnosis," and illustrated his very interesting talk with numerous slides. Among others, the conditions that excited most interest were pseudoneuritis, aplasia of the optic nerve, hyaline bodies of the disc, holes in the disc, and the ophthalmoscopic differentiation of papilledema and optic neuritis.

Dr. Walsh described some of the abnormalities of the optic disc which cause confusion in diagnosis. Most of the anomalies selected for consideration have been confused from time to time with papilledema associated with increased intracranial pressure.

His criteria for the diagnosis of papilledema associated with increased intracranial pressure were: (1) Absence of pulsations of the vein on the disc, (2) measurable amount of papilledema, (3) the presence of exudates or hemorrhages, (4) presence of pallor of the swollen disc, (5) marked narrowing of retinal vessels, and (6) transient blurring of vision.

The ophthalmologist should be the examiner, Dr. Walsh stated, who briefly refutes the diagnosis of papilledema, and explains the presence of the apparent choking in conditions like persistent Bergmeister's papilla, hyaloid cyst, hyaline bodies, high hyperopia, and tilting of optic discs. He placed particular emphasis on the subject of hyaline bodies in the discs, their appearance, and the field defects with which they are sometimes associated. Costen was quoted as saying that there seems no question regarding progress of the field defects.

Dr. Walsh's paper was discussed by Dr. Benjamin Rones, and questions were proposed from the floor by Mrs. Helenor Wilder, Dr. Sterling Bockoven, Dr. David Cogan, Dr. Edward Cummings, Dr. O. H. Fulcher, Dr. Joseph Kemler, Dr. H. V. Rizzoli, Dr. Ernest Sheppard, Dr. G. Victor Simpson, Dr. Harold Stevens, and Dr. Jonathan M. Williams.

PERSISTENT HYALOID ARTERY

Dr. William Kuhlman presented M. V., a girl, aged 10 years. She had been an eighth month premature, weighing 3½ pounds at birth. At 3 months she had an obstructive jaundice. At present she is well, but has spastic movements and is mentally subnormal. Vision in the left eye is 20/100. The left lens is clear. Extending from the disc to the lens is an entire central hyaloid artery in a thin membrane. The artery breaks up into branches as it nears the lens.

KERATITIS WITH IRIDOCYCLITIS

Dr. von Haller Brobeck and Dr. Sam Brown presented Mr. N. C. R., aged 57 years. On December 9, 1946, he was seen with a corneal ulcer with keratitis. The ulcer was cauterized with iodine and the eye kept atropinized. The ulcer healed, leaving two scars in the center of the cornea.

On May 11, 1948, he returned, again complaining of pain in the right eye. Vision in the right eye was 20/40. A central keratitis was present. No history of tuberculosis was elicited. Physical examination was negative. Reaction to tuberculin was markedly positive. The pupil was dilated with atropine and typhoid-H antigen was given intravenously. In June, since no improvement had taken place, a course of penicillin treatment was given, and whole blood was instilled into the eye. An iridocyclitis developed. Salicylates were given orally. The vision decreased to perception of large objects only. The thermophore was used on the cornea. In August, an abscess developed in the anterior chamber. A keratotomy was performed and culture of the pus showed Staphylococcus albus. Since then there has been no pain but the eye continues very red. Vision is reduced to seeing large objects.

Discussion. Dr. William Kuhlman said that he had had this patient in the hospital for 10 days under streptomycin therapy. The eye cleared while under treatment. Perhaps, if it had been continued, there would have been more clearing.

Colonel Martin said that, in his experience, while streptomycin is being given, the eye clears but, when it is stopped, the infection starts up again. He considers that the bacterial invasion has been stopped but no immunity built up. He uses 1 gm. a day in divided doses for 30 days, than 0.5 gm. a day for 90 days.

Dr. George Brown suggested X-ray treatment. Dr. James Rigg said that carbuncles clear when penicillin is injected in the tissue around. He suggested retrobulbar and circumcorneal injection of streptomycin or penicillin.

Dr. George Stine saw the patient in consultation two years ago. It was a compensation case, the cornea having been scratched by a box while the patient was at work. At that time he had a small, irritable, sharply delimited opacity. It is a bizarre keratitis, probably a tuberculous process.

Dr. Morris Kaplan had tried injecting penicillin into the anterior chamber but a severe reaction had taken place. Colonel Martin suggested that it might be possible to introduce penicillin into the anterior chamber by iontophoresis. This treatment has produced a reasonable clearing of a sclerosing keratitis of 11 years' duration. It is useful in corneal and iritic lesions.

BAND-SHAPED KERATITIS

DR. VON HALLER BROBECK and DR. SAM BROWN presented Mr. J. S., aged 36 years. The right eye has had an opacity since childhood. About eight years ago a similar opacity began to appear in the left eye. It had become much more dense in the past year. Vision is: R.E., 20/60; L.E., 20/50, with or without glasses. Each cornea has a dense horizontal band across the center with clear cornea above and below. Each iris is markedly atrophic. On June 25, 1948, the scar was resected. During the operation, the cornea was perforated and a conjunctival flap was drawn over it. When the flap retracted, a pseudopterygium remained. On August 9, 1948, this was removed. Following this, a good cosmetic result was obtained. On September 3rd, nutrient vessels leading into the scar were cauterized with trichloracetic acid. At this time a descemetocele was beginning to form in the upper outer area of the cornea.

CENTRAL CHOROIDITIS

DR. F. NELSON presented Mr. R. H., a Negro aged 46 years. One year ago he was seen by several other oculists over a period of several months because vision in the right eye had started to blur. No objective pathologic condition was found at that time. When the patient was seen on June 17, 1948, vision of the right eye was reduced to 5/18, partly. A central scotoma was present. Ophthalmoscopically an extensive destructive process was found in the right macula which appeared to be punched out. A sausagelike hemorrhage surrounded the macular region below and nasally. This hemorrhage was

subretinal and the vessels could be seen climbing over it. An incomplete white star figure was between disc and macula and below the macula. The left eye was normal.

Physical examination revealed several dental abscesses, the largest one, located above the upper right molars, measured 2.5 by 1.5 cm. All pus cysts were removed from the patient's jaw and the retinal process then cleared up gradually. On August 20th, vision was 5/15, partly.

In cases of central scotoma with deterioration of vision and no evidence of retrobulbar neuritis the macular region of the affected eyes must be checked over a long period of time. A search for focal infections is especially indicated in such cases.

CENTRAL CHORIORETINITIS

DR. GEORGE H. STINE and DR. KATHARINE H. CHAPMAN presented two cases of old healed central chorioretinitis in which the patients were not conscious of having any trouble. K. K., a boy, aged 15 years, first noticed last summer that his right vision was blurred. He had never had any discomfort in his eyes. He has always shot with the gun at his left shoulder. He writes with his left hand. At about three years of age he had a severe pneumonia. Vision is: R.E., 20/200; L.E., 20/12. The right macula has an area of choroidal atrophy, 1 p. d. in diameter, with irregular pigmented margins.

Mrs. C. G., aged 31 years, a housewife, had noticed some dimness of vision with pain in the left eye for a few days about 10 years ago. No oculist was consulted at that time, and only recently had she noticed that she could not see to read with the left eye. Vision is: R.E., 20/25.; L.E., 4/300. The left eye has a large chorioretinitic scar in the macula. The right eye has a small area of choroidal atrophy with pigment, nasal to the disc.

Secretary.

MEMPHIS SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

June 8, 1948

LEUKEMIC INFILTRATION OF ORBIT

DR. J. WESLEY McKINNEY reported the case of J. H., aged 5 months, who was referred for removal of a tumor of the right lower lid. The parents first noticed a redness and then a lump in the right lower lid which had progressively enlarged for one month. The child was otherwise apparently well. There was a firm mass involving most of the floor of the right orbit. The mass was not attached to the skin but attached to the periosteum. The lower lid was bulged outward and the eyeball displaced upward slightly. The globe was internally and externally normal. The other eye and orbit were normal. The baby was sent to a local pediatrician for general physical examination. He reported a white blood count of 105,000, with 98-percent lymphocytes, and severe anemia. He made the diagnosis of acute lymphatic leukemia. The child died within two weeks.

ECZEMATOUS KERATITIS

DR. J. WESLEY McKINNEY reported the case of Dr. M. C., aged 32 years. She gave the history of having repeated ulcers of the left cornea for the past four years. For the past six months the eye had been slightly injected and irritated to such an extent that she was able to carry on her work with difficulty. She was a resident physician at the Cleveland Clinic and had had many examinations and had tried many forms of treatment. Physical examinations were negative except for a low basal metabolism rate for which she was taking 3 gr. of thyroid daily. She was allergic and had been found sensitive to many things. Desensitization with various allergens gave no relief. Among the medications tried were vitamins generally and locally, riboflavin injections intrave-

.nously, adrenalin drops, holocaine and sulfathiazole ointments. She was finally advised to leave Cleveland.

When first seen here, the right eye was entirely normal. The epithelium of the left cornea showed widespread stippling of the cornea. Almost the entire corneal surface stained with fluorescein. There was only slight pericorneal injection and moderate blepharospasm. Corneal sensitivity was slightly reduced. With the use of a protective goggle, which allowed a minimum of air to reach the cornea, the condition cleared to some extent and the staining areas fluctuated in size from time to time. During this time all medication was stopped. The patient, however, was never free from discomfort.

It was finally decided to try X-ray therapy on the basis of the good results often obtained in eczema of lids. A total of 600 r. was given in 6 equal doses at 4-day intervals. There was a moderately severe conjunctival reaction to the X rays which lasted about four weeks. During this time the stippling of the corneal epithelium could still be seen but there was no staining. The patient reported being entirely comfortable. One month later the corneal epithelium was entirely clear and there was no discmofort. Two months later or four months after the X-ray therapy, there had been no return of symptoms and the cornea was entirely clear.

CENTRAL SCOTOMA DUE TO PITUITARY TUMOR

DR. RALPH O. RYCHENER presented R. P. S., a man, aged 25 years, who, two months previously, had discovered a loss of central vision in the left eye. Various examinations were done in his own city and he was seen at the Veterans Bureau at Jackson, Mississippi, where removal of the left eye was advised because of intraocular sarcoma. Examination disclosed normal vision, visual field, and normal eye grounds in the right eye. Vision in the left eye was reduced to moving objects and the field was inconclusive, although central vision was definitely lost. The fundus of the eye was heavily tessellated and, at the periphery far above, there was a dense accumulation of choroidal pigment which was interpreted as a benign melanoma.

The patient was returned to his referring physician, Dr. J. C. Pegues of Greenwood, Mississippi, and was advised to have a course of treatment consisting of foreign protein and vasodilators, since the condition seemed to be a retrobulbar neuritis. At the completion of this treatment, there was no visual change and he was seen again in Jackson, Mississippi, where the advice of the removal of the eye was reiterated.

Upon the patient's return to Memphis the same diagnosis was made as on the previous visit and he was admitted to the Eye, Ear, Nose, and Throat Hospital for further foreign protein and vasodilator therapy. At the conclusion of this treatment, vision in the left eye returned to 6/60, J12. At this time the form and color fields disclosed a temporal hemianopia in the left eye and a relative hemianopia in the right eye. Diagnosis was then changed to that of a pituitary lesion. X-ray films disclosed an eroding pituitary tumor and on May 11th, Dr. Nick Gotten removed a chromophobic adenoma of this gland.

Visual improvement was almost immediate and, within two weeks, it had returned to 6/6, J1 in the left eye, with slight improvement in the visual field and a residual pallor of the temporal portion of the optic disc. X-ray therapy through four portals is completing the treatment.

PROGRESSIVE ENLARGEMENT OF FILTRATION BLEB FOLLOWING IRIDENCLEISIS

DR. PHILIP MERIWETHER LEWIS presented a white woman, aged 52 years, with an increasingly large corneal bleb following operation for glaucoma.

On August 16, 1945, the right eye began to pain and, when seen the following day, was stony hard with vision reduced to hand movements. Treatment with eserine, pro-

stigmin, and mecholyl failed to lower the pressure. Iridencleisis was performed, the scleral incision being made ab externo, approximately 1.5 mm. from the limbus. The iris prolapsed, was split meridionally, and both pillars incarcerated into the angles of the wound. Convalescence was uneventful, the pressure remaining around 20 mm. Hg (Schiøtz) for about a month. Vision returned only to 20/70, which was partially due to some early lens opacities. Six weeks after operation the tension was only 12 mm. Hg and the filtration bleb was quite prominent, but did not extend forward past the limbus. Vision was 20/70. The left eye was normal.

The patient was not seen for seven months (April, 1946) at which time vision and tension were the same, but the bleb was uncommonly large and extended slightly into the cornea. She was asked to return every few months, but did not come back for over a year (July, 1947). She then had an acute attack of glaucoma in her left eye. Reduction of pressure could not be obtained by strong miotics, so an iridencleisis was performed. The anterior chamber did not restore for 10 days and has remained shallow ever since. Vision could not be improved to better than 20/100 after operation and the gradual development of a cataract reduced it to 15/200.

The bleb of the left eye was larger than average, but small in comparison to that of the right. The bleb of the left eye now extended 1 mm. over the limbus into the cornea; that of the right extended 4.5 mm. downward toward the pupil—from the 10- to 2-o'clock positions on the limbus, a distance of 13 mm.—and it was more than 2 mm. thick. It formed a mass that was uncomfortable to the patient and disfiguring. The tension could not be measured due to the bleb covering more than one third of the cornea. Tension of the left eye was 8 mm. Hg and that of the right eye seemed about the same to palpation. The patient was reluctant to undergo further surgery, but it

was felt to be necessary, as the bleb was destroying the cornea, dissecting it somewhat in the manner of an aneurysm. Removal of the corneal portion of the bleb, curettage of the upper part of the cornea, and the drawing down of a conjunctival flap have been contemplated. Possibly cauterization of the upper cornea should be done to try to secure a firm cicatrix and to prevent a recurrence of the enormous corneal bleb.

Daniel F. Fisher,
Recorder for Eye Section.

OPHTHALMOLOGICAL SOCIETY OF MADRID

April 16, 1948

FATTY DEGENERATION OF CORNEA

DR. MARIN AMAT read a paper on two cases of fatty degeneration of the cornea following herpes corneae, one traumatic, the other spontaneous.

In both cases there was a rapid infiltration of fat in the whole cornea, during a period of two to three weeks, with complete loss of vision. It thus appears that herpes corneae predisposes the eye to such fatty infiltration. The fact that one case was due to an accident while the patient was at work gives it great importance from a legal standpoint.

In connection with these cases, Dr. Marin Amat discussed the presence of fatty substances in the cornea as possibly being caused either by a simple accumulation of fat occurring normally in the circulation, or by the production in situ of lipoids caused by foreign substances stimulating the tissues. In exceptional cases it may be due to an excessive quantity of fat in the circulating blood.

The fatty substance is found in a very fine emulsion in the blood stream and in the cells, constituting an integral part of the protoplasm and participating in its activities, though to a minor extent, since it is continually destroyed by the intracellular

oxidase. But if the oxidation is deficient, the fine emulsion of neutral fat and of cholesterol condenses and gives the typical picture of fatty degeneration.

Thus this process can be caused by local, insufficient oxidation, by excessive cholesterol in the diet, or by a disturbance of lipoid metabolism. In accordance with these concepts, Dr. Marin Amat suggested applying locally substances which provide abundant oxygen to the corneal tissues.

Discussion. Dr. Mario Esteban said that Dr. Marin Amat's paper touched on a topic of great practical interest since little is known of the intimate mechanism of local and general metabolic disturbances which lead to the fatty degeneration of the cornea. The therapeutic suggestions are scientifically sound and should be investigated, especially as we are now powerless to stop these processes.

Dr. Marin Amat agreed with Dr. Mario Esteban that secondary fatty degeneration of the cornea is a relatively frequent complication, but he does not know of any published case of its following herpes corneae. In addition, herpes corneae is considered an occupational disease when it accompanies or follows ocular trauma. Moreover, it seems that the herpes virus tends to dispose the corneal tissue to fatty degeneration.

RETINAL DETACHMENT DIAGNOSED AS RETROBULBAR NEURITIS

DR. CARRERAS-MATAS described a case of a woman patient whose only symptom was a central scotoma. The ophthalmoscope showed no alteration at the posterior pole of the fundus which could explain the scotoma, and it was diagnosed as retrobulbar neuritis.

Several days later, the scotoma became denser and spread to the periphery. The ophthalmoscope showed a retinal detachment with a very minute tear in the centrocecal region.

Dr. Marin Amat said that a small retinal detachment may be confused in the beginning, because of the central scotoma, with retrobulbar optic neuritis, since the papillomacular bundle is involved in the neuritis. In the case described the papillomacular bundle was also involved by the slight edema and the subsequent detachment of the retina, which in the beginning could not have been detected.

The only difference which may be mentioned is that, in optic neuritis, the papillomacular bundle is affected in its course in the optic nerve and, in this case, in its course between the fovea and the papilla.

It is evident that the blue blindness which the detached zones of the retina show, which in turn is a form of hemeralopia, can also be explored by perimetry.

In the days when there was no operation for retinal detachment and the detachments became larger and more fixed, it was common observation that the patients would tell us when the retina became adherent. Although they could not see the color of the sky during the day, in the morning on opening the window they were enthused on seeing the beautiful, intense blue color of the sky. What happened was that, during the night, with the absorption of the subretinal edema, the retina became attached, although only for a transitory period.

John I. Pascal,
Translator.

THE JUNE MEETINGS

The American Ophthalmological Society held its 85th annual meeting at Hot Springs, Virginia, on June 2nd to 4th. The weather was perfect, the surroundings beautiful, comradeship evident, and the program highly satisfactory and instructive. There were 120 members and 29 guests in attendance, and 21 scientific papers were read and discussed. Most of these were meritorious and several were particularly noteworthy.

To mention briefly a few, Dunnington discussed late fistulization of operative wounds and described an operation by suture to close the fistula. Cordes described bilateral malignant ocular melanoma. Joy's paper on nevus flammeus associated with glaucoma added further evidence that increased capillary permeability may occur in the condition.

Scheie presented further evidence that goniotomy is efficient in congenital glaucoma. Reese contributed valuable material to the subject of spontaneous cysts of the ciliary body simulating neoplasms. Prof. G. B. Bietti, of Pavia, and Gundersen's paper on the use of para-amino-salicylic acid and streptomycin was well received.

One of the most interesting papers was

that by Dunphy on ocular conditions associated with idiopathic hyperlipemia. Dr. Bedell had some beautiful retinal Kodachromes, as usual, to illustrate his discussion of retinitis punctata albescens. Fink's contribution on the anatomic approach to surgery of the oblique muscles was convincing and valuable.

These papers and others similarly important produced lively discussions which often developed points of interest and instruction that were as significant, or at times more so, as many presented by the essayists.

The Howe Medal, which hereafter will be known as the Distinguished Service Medal of the society, was granted to Phillips Thygeson of California for his outstanding contributions to the field of ophthalmic bacteriology and virus diseases.

Parker Heath of Boston was elected the president, and John H. Dunnington of New York, the vice-president. The retiring president, Bernard Samuels, presented a beautiful chain and badge of office to the society, and graciously hung it about the neck of the incoming president.

The members of the society unanimously adopted a by-law to the constitution whereby a member found guilty of accepting rebates would forfeit his membership in the society. This is the first national ophthalmic organization to take this important and long-delayed stand.

Most of the members moved on to Philadelphia to attend the 18th scientific meeting of the Association for Research in Ophthalmology which was held on June 6th and 7th. At this meeting, 18 splendid papers of strictly research interest were given. Of these, the papers by Collins on "Experimental studies on sympathetic ophthalmia," and Smelser and von Sallmann on the "Correlation of microscopic and slitlamp examination of developing hereditary cataracts in mice," von Sallmann and Dillon on "Studies of the eye with radioiodine autographs," Kinsey on "A study of the possible conversion of dehydroascorbic acid to ascorbic acid in the aqueous

humor," Koelle and Friedenwald on "The histochemical localization of cholinesterase," and Day on "Polysaccharides in ocular tissue," were particularly outstanding.

Wilson evaluated a radium-D applicator that has been widely sold and leased to ophthalmologists and pointed out that it has a low output and superficial penetration. An increase in the dosage of radium D to obtain adequate irradiation of deeper tissues would produce more damage superficially than radon or radium.

William F. Hughes, Jr., was elected the new trustee. Most of the 150 members registered stayed throughout the entire meeting, and one could not help but be impressed by the growth, enthusiasm, and great significance of this organization. There is no question that outstanding work in experimental ophthalmology is being accomplished by an increasing number of investigators who are native born and trained. The best of the new work appears to be done in the few "institute" type of organizations that are available in this country.

The Section on Ophthalmology of the American Medical Association held its annual session on June 8th to 10th at Atlantic City. There were 450 members of the section registered, although the audience at times was greater than this number.

M. Hayward Post, Jr., the chairman, in his address discussed the functions of the various national organizations in this country with particular reference to that of the section. He pointed out the key position in American ophthalmology occupied by the section and its importance to ophthalmologists.

A symposium on ocular injuries, put on the program at the request of the Surgeon General of the Army, followed Dr. Post's address. It was well received, and should be useful to the armed forces and to the general practitioners for future reference.

Ten scientific papers of excellent merit were given during the rest of the session. These were well discussed not only by the

official discussors but by members from the floor, as well. The subject of retrolental fibroplasia was reviewed by King and also by Heath who spoke on its pathologic aspects.

Among other noteworthy papers were those by Cowan and Klauder on "The frequency of the occurrence of cataract in atopic dermatitis," Bietti on "New trends in ciliary body surgery for the relief of glaucoma," and Sanders and Cutler on "General anesthesia for cataract surgery."

Ray A. Irvine of Los Angeles and Albert LeMoine, Sr., of Kansas City were elected chairman and vice chairman, respectively. Dr. Conrad Berens of New York was awarded the Scientific Medal of the section for his many important contributions to ophthalmology.

The section was represented by eight exhibits, all excellent, in the Scientific Exhibition of the parent organization. Of these, the exhibit by A. L. Kornzweig, of New York, on the pathology of the eye in old age received the Silver Medal of the association for Group II, and that of Peter Kronfeld, Roy Riser, and John Parker of Chicago, on glaucomatous excavations, a Certificate of Merit, Group II.

In making the busy round of these meetings, one is convinced that our science in this country is growing by leaps and bounds. Earnest and eager workers are increasing in numbers. The scientific and literary merit of their contributions is on a very high level of integrity and truth. The stimulation of hearing them is almost overwhelming and mildly depressing, especially to those of a slightly lazy nature. However, those who attended the meetings will, no doubt, return to their work determined to improve the quality of their activities and refreshed by their experience.   Derrick Vail.

WILMER RESIDENT'S MEETING

The Wilmer Resident's Association held its eighth clinical meeting at The Johns Hopkins Hospital and University on April 6,

7, and 8, 1949. The association is composed of former senior residents of the Wilmer Ophthalmological Institute. Their annual clinical meeting provides an opportunity to review the work done in the institute during the past year, and to follow the activities of the former residents.

The program indicated the scope of the research which is in progress at the institute and was organized to present subjects of interest to the clinician and to the investigator as well. The influence of Dr. Alan C. Woods, the director, and of Dr. Jonas S. Friedenwald pervaded the meeting. Dr. Frederick Verhoeff was in constant attendance and took every available opportunity to present the "Boston" point of view in his inimitable discussion which delighted the group.

Dr. Woods presented what was in substance a symposium on uveitis. His three papers were entitled: "Classification and special symptomatology of uveitis," "The etiological diagnosis of uveitis," and "Treatment of uveitis." The granulomatous and nongranulomatous types of uveitis were clearly differentiated. Repeated attacks of nongranulomatous uveitis can produce vascular damage, thrombosis, and necrosis and, with subsequent repair, give a picture of plastic iritis which may superficially resemble granulomatous uveitis. Dr. Woods interprets this vascular damage as a manifestation of the Arthus phenomenon.

Granulomatous uveitis usually can be diagnosed and the etiology presumptively determined. An exception is in the case of chronic brucellosis. During the past year the armamentarium for indicating toxoplasmosis has been enhanced. The skin test of Frenkel, indicating sensitivity, and the methylene-blue dye test of Sabin show good correlation in evidence of the presence of neutralizing antibodies in the patient's blood. Sabin prefers the dye test to the rabbit test he formerly employed.

New possibilities for the treatment of uveitis are accumulating. Streptomycin,

promin and promizole in tuberculosis, aureomycin in brucellosis, penicillin in syphilis, and desensitization to bacteria causing the nongranulomatous type of the disease, are the outstanding examples. There is no question about the miraculous effect of penicillin on syphilitic uveitis. In other instances of the disease, penicillin is of no value and the promiscuous use of this antibiotic in cases not due to syphilis was censured. The final evaluations of streptomycin, promizole, and aureomycin await further clinical trial. The use of these and other new drugs and antibiotics was further discussed by Dr. Perrin Long in "Modern status of antibiotics."

In nongranulomatous uveitis due to sensitivity to streptococci, gonococci, and staphylococci, treatment by desensitization, particularly to specific strains of streptococci, is an approach to the problem that is being re-emphasized. In some cases desensitization to specific organisms found in foci of infection is being carried on with encouraging results.

Putting time and effort into the study of each uveitis case, tracking down the etiology before instituting treatment, according to a rigid and carefully planned attack, as is done at the Wilmer Institute, is the only way the problems of this disease can ever be solved or judicious treatment be prescribed.

A fascinating paper by Dr. Malcolm W. Bick and Dr. Ronald Wood on "Heparin and ocular sensitivity" may prove to have a bearing on the problem of uveitis. They showed that heparinizing animals minimized or overcame induced states of hypersensitivity. Additional work along the lines of this investigation would seem to have great potentialities of application.

The perplexing and disheartening problems of uveitis are gradually being reduced, by such investigation as is being carried on at Wilmer, to more basic factors of tissue and humoral reactivity, and therapeutic measures are becoming accordingly more specific. The organization of uveitis services throughout the country, along the lines prescribed by Dr. Woods, would inestimably facilitate the care and cure of patients afflicted with this disabling disease. The goal is far from sight, but I predict that the tenacious and Herculean efforts of Alan C. Woods are setting the course and pattern for its realization.

"Sympathetic ophthalmia following intraocular surgery" was the subject of Dr. Howard A. Naquin of the resident staff. He analyzed 35 cases proved by pathologic examination. Many of these were operated on elsewhere than at Wilmer. In all cases there was evidence of incarceration of uveal pigment in the wound. The impression was that early enucleation of the activating eye has a favorable effect on the course of the disease. This is contrary to several previously reported investigations, particularly one which the author conducted in 1937. Further observations are warranted, as analyzing all cases in the literature where sympathetic ophthalmia is reported to have become apparent only after the exciting eye had been removed, and this eye revealing evidence of the specific infiltrate.

Dr. Jack S. Guyton, assistant director of the Wilmer Institute and associate professor of ophthalmology, read two papers on strabismus. The first, entitled "Surgical correction of horizontal strabismus: A new concept of the mechanics involved," emphasized the varying effect of the vertical muscles, particularly the obliques, on horizontal rotation as the eye is rotated laterally different degrees. The concept is based on mathematical formulas which heretofore have not been applied to the mechanics of ocular rotation. Application of Guyton's idea may lead to a more accurate estimation of the effects one may expect from recession, resection, and advancements. A simple mathematical formula to be used in surgery combined with a proper understanding of innervational factors is sorely needed if the results of strabismus surgery are ever to be uniformly predictable. His second paper, "Surgery of the horizontal recti: approach through a concealed conjunctival incision," demon-

strated a simple way to avoid unsightly scars without unnecessarily complicating the surgery.

Four papers dealt with the subject of glaucoma. The first of these was "Some ocular effects of a new anticholinesterase agent, tetraethyl pyrophosphate (T.E.P.P.)." Dr. William G. Marr, the present senior resident, presented evidence that this drug may cause detachment of the retina through extreme contraction of the ciliary muscle, and also that sensitivity reactions to this drug are so excessive as to preclude its clinical use at present.

Dr. Angus L. MacLean presented a method of "Corneoscleral trephine and intracapsular extraction in one procedure for primary glaucoma combined with cataract." Motion pictures were used to illustrate the procedure. The use of a Berens's punch in place of a trephine might possibly simplify the technique.

"The results of surgery in acute glaucoma" were analyzed by Dr. Herman K. Goldberg. Simple iridectomy was a satisfactory operation if the patient was being treated for a first attack of glaucoma. After a second attack, some type of iris-inclusion operation combined with separation of the iris at its base gave the best results. The last paper on glaucoma was "Changes in intraocular pressure following miotics," by Dr. Rufus C. Goodwin.

Two outstanding papers undoubtedly were inspired by the research of Friedenwald utilizing histochemical techniques for the study of physiology of the eye. The first, by Dr. Robert Day, "Polysaccharides in ocular tissue" dealt primarily with the distribution of polysaccharides and the effect of the enzymes, hyaluronidase and amylase, in depolymerizing these polysaccharides in the eye. The second, by Dr. George B. Koelle, was "Histochemical localization of choline esterase in ocular tissue."

Dr. Jonas Friedenwald's significant contribution was entitled "Inhibition of mitosis in the corneal epithelium by ionizing radiation."

His experiments suggest that X rays inhibit cell division through chemical changes produced in the cells rather than through direct ionization of some component of the mitotic mechanism.

Dr. Roy O. Scholz concluded from his data on "Use of radioactive indicators for study of aqueous humor" that the aqueous is a secretion. He determined the concentration of radioactive sodium in the serum and the aqueous with the lids open and then with the lids closed.

Dr. Robert C. Laughlin, now associate professor of ophthalmology at the new medical school of the University of Washington, reported his interesting observation on "A new variety of corneal pigmentation" in workers in factories making poisonous gas. Approximately 50 percent of the employees in these factories showed what appeared as a Stahli's line in the cornea.

"New radon and radium-D applicators" were discussed by Dr. William F. Hughes, Jr. He has devised one in which small glass vials of radon gas are imbedded in beeswax in the tip of the applicator. The dosage can be varied by varying the number of vials used. Beta radiation, so applied, can obliterate vessels deep in the cornea, and the radiation is sufficiently strong so that it need be applied only for a very brief duration. Dr. Hughes explained that the radon-D applicators on the market give off a soft Beta radiation that can be used for surface-fire effect, but not effectively for destroying vessels deep in the cornea. The new applicator he described can be used for deep or superficial effect, and the time of application can be very short.

In "Cataract section following filtering operations," Dr. Russell T. Snip reviewed the results of such operations performed at the institute to determine which type of section affected the drainage least and produced fewest corneal changes. A corneal section away from the filtration bleb, rather than through it, was least detrimental to subsequent drainage in the eye. Sections above or

to one side, or below, in the cornea showed no appreciable difference in the incidence of subsequent dystrophic changes in the cornea.

Dr. Frank B. Walsh presented a masterful treatise on "The anatomy of neurologic defects in pituitary tumor." Diagrams and illustrations depicted clearly the anatomic basis for various signs and symptoms of pituitary disorders.

A thorough study of "The effect of retrobulbar alcohol injection on the eyes of experimental animals" was made by Dr. Walter Kornblueth, who was formerly at Wilmer and is now working at Stanford under the direction of Dr. Alfred E. Maumenee, the former Wilmer resident who is now professor of ophthalmology at Stanford Medical School. In the experimental animals, repair processes in the cornea were definitely inhibited by the retrobulbar injection of alcohol. The significance of this finding may not be as ominous as one might suppose, for clinical reports on patients reveal no alarming complications following such injections. However, this new experimental evidence should put the clinician on guard.

It was interesting to hear Dr. Walter H. Benedict discuss "Prognosis for vision in anoxia," because of the content of the paper and the manner of presentation, and, in addition, because of his resemblance to a certain well-known ophthalmologist from the Middle West who was an attentive listener.

From the department of physiological optics, Dr. Louise L. Sloan and Miss Lorraine Wollach reported on "Total color blindness."

In the field of electrophysiology Dr. Carlton C. Hunt, Dr. Stephen W. Kuffler, and Dr. Samuel Talbot demonstrated "New retinal recording methods from the intact eye." Action currents were recorded from single nerve elements.

A collection of fundus and external eye pictures were exhibited in the institute during the meetings. These drawings were made by Annette S. Burgess and represent the finest collection of fundus drawings in the country. Many hours could be profitably spent studying these pictures.

The outstanding single presentation at this meeting was that of Dr. William C. Owens and Dr. Ella Uhler Owens. The title was "Vitamin-E studies in relation to retrolental fibroplasia." These workers have already proved that retrolental fibroplasia is an acquired condition, first manifesting itself about two months after birth as dilatation of the retinal vessels with subsequent edema and exudate of the retina, then separation of the retina into peripheral folds that become organized behind the lens, finally forming a gray membrane. Because the condition is acquired, some factor in the care of prematures was suspected in the etiology. Because of the presumed poor assimilation of fats by the premature infant and because of the anemia and growth requirements, the accepted treatment in recent years has included high protein diet with high vitamin-A and iron intake. It has been shown that in some animals, particularly in chicks, high doses of vitamin A and iron inhibit the availability of vitamin E, resulting in a relative deficiency of E, leading to nutritional encephalomalacia.

No such clinical entity as vitamin-E deficiency has been recognized in humans, but the facts in experiments with chicks led the Drs. Owens to believe that deficiency in available vitamin E might be a factor in the development of retrolental fibroplasia.

Three groups of prematures were observed. The first group were treated in the usual way and the incidence of retrolental fibroplasia was the usual figure of 12 to 25 percent. A second group were given a new water-miscible vitamin-E preparation and less vitamin A and less iron than the first group. No instance of development of the condition was seen in this group. A third group, in whom the disease was just becoming apparent, were treated with addition of vitamin E and reduction in vitamin A and iron intake

and regression or cure of the disease resulted.

In discussing this paper Dr. Kinsey of the Howe Laboratory paid tribute to the accomplishments of the Drs. Owens as showing perspicacity of the highest order in the plan of investigation and the analysis of results, and he said that, in his opinion, those privileged to be present had witnessed an epochal contribution. It remains a mystery why the incidence of the condition is much higher in Boston, Baltimore, and Chicago than in some other cities, as for instance, Los Angeles, when the accepted modern treatment of prematures includes correspondingly high doses of vitamin A and of iron in all localities.

It is to be hoped that many of these fine papers will soon be published, for they are worthy of a nationwide audience.

S. Rodman Irvine.

BIFOCALS FOR JUVENILES

Not infrequent are misconceptions as to the care and significance of presbyopia and as to the prescription of bifocals. In infancy the healthy crystalline lens is so nearly fluid that its consistency presents no appreciable obstacle to the changes necessary in accommodation. If the eye is approximately emmetropic, all that is necessary for accurate vision of near objects is such an amount of activity of the ciliary muscle as will produce the proper increase of convexity of the crystalline lens. If the eye is made emmetropic by proper correction of hyperopia, myopia, or astigmatism, the same sort of physiologic need is satisfied by the same sort of action on the part of the ciliary muscle. Apart from uncorrected refractive error, this physiologic effort of accommodation normally causes no symptoms and is not harmful to the patient.

There used to be a rather general notion that the hyperopic patient possessed more, and the myopic patient less, than the normal capacity for accommodation. More exact study has shown this not to be the case. The myopic patient's accommodation, in the presence of an accurate distance correction, is normally as ample as that of the emmetropic or hyperopic patient under similar conditions of age and general vitality. Thus it is a mistake to assume that the properly corrected myopic child or adult is less equal to the task of reading, writing, or drawing than other properly corrected children.

Exact measurement and recording of the patient's accommodation is too generally neglected or carelessly undertaken. It should preferably be indicated in diopters on the basis of the least distance at which the patient can still see sharply (even with effort if necessary) the smallest detail of type or other fine test object which can be made out at such distance; the test being made either without or with correction, or with a presbyopic addition, according to the circumstances of the case.

Statements have been made as to the influence of convergence in relation to the myopic eye, but there is no adequate evidence as to the significance of any such relationship. Nor is there, in spite of all that has been said as to the effect of near work in the production of myopia, any proof that the mere exercise of accommodation, apart from the bearing of posture and other conditions upon the general health, is capable of damage to the young eye.

In the normal course of life the crystalline lens steadily becomes less fluid or elastic, and the near point of accommodation gradually recedes from the eye, until at last the eye is no longer capable of sufficient adjustment to provide for the ordinary range of close work, especially reading or sewing. In most eyes with proper distance correction this stage is reached somewhere around the age of 45 years.

It used to be rather customary to lay down a "rule of thumb" that the patient should be given (over and above his distance correction) about one diopter of plus spherical

addition at the age of 45 years, two diopters at 50, two and a half diopters at 55, and three diopters at 60 years. These figures are more or less excessive for most people, and were quite certainly dependent upon the fact that it was formerly much less usual to give patients adequate basic correction for hyperopia, so that they were regarded as being more presbyopic than they actually were. With proper distance correction, most people can manage very well with a 2.25 diopter near addition until well beyond the age of 60 years.

Every accurate ophthalmologist encounters from time to time a patient who has been given a bifocal addition unnecessarily. In the experience of the present writer, such cases have usually been those in which the basic hyperopia was inadequately corrected. More rare, to most of us, is the experience of seeing bifocals placed on young children. Now and then we have to do with an optician's or optometrist's prescription for a case of strabismus in which the distant correction has been grossly underestimated.

According to an ophthalmologist correspondent in the Middle West of the United States, there is in his vicinity a sort of "epidemic" of the furnishing of bifocals to cases of high myopia, or even sometimes to cases of only moderate myopia. This practice is seen, according to our correspondent's experience, among the respectable type of optometrist, and is explained as due to lectures given under a so-called "optometric extension program."

As examples of the practice are listed patients of ages ranging from 10 to 20 years, and with myopic errors running from minus 0.25 sphere through minus 1 or 2 diopters and up to 4 or 5 diopters. All the patients listed had excellent visual acuity, accommodation, and convergence. They were always grateful for withdrawal of the bifocal addition.

In defense of such a practice, the optometrist responsible was disposed to urge the frequent suggestion in older textbooks that the myopic correction prescribed for distance should be reduced for near work. It may be added that this older advise is more or less vaguely excused in some more recent publications.

The cause of marked differences in refraction, in families in which the hereditary factor is not clearly responsible, is far from being definitely understood, but there is good reason to suppose that it has something to do with an increased hereditary capacity for variation in the family or individual, especially in the period of active growth. It is now general practice to prescribe a full correction for this refractive anomaly, although of course with precise attention to astigmatic errors and inequality of the two eyes, as well as extreme accuracy in the placing of the lenses. The present writer has followed this procedure in very many cases of high or moderate myopia, in children usually healthy and physically vigorous, and has never seen cause to regret doing so. Nor, in adopting such a course, is it necessary to take the patient out of school. The rapid progression in amount of myopia frequently seen is almost certain to become much less marked at the close of the period of active growth.

One rather important point commonly overlooked is that the patient with an uncorrected low amount of myopia may suffer from eyestrain caused by habitual cramping of the lid muscles in the instinctive effort to sharpen vision.

Although, let us hope, usually done with a clear professional conscience, the ordering of bifocal glasses for myopic children is not only unnecessary but objectionable, and suggests in the prescriber a lack of scientific understanding of ocular physiology. The satisfaction subsequently created by withdrawal of the presbyopic element at the hands of an enlightened ophthalmologist must be somewhat disturbing to the reputation of the optometrist concerned.

W. H. Crisp.

OBITUARIES
ARTHUR N. ALLING
(1862-1949)

Dr. Arthur Nathaniel Alling was born in New Haven, Connecticut, July 1, 1862, of an old New England family. He prepared for college at the Hopkins Grammar School and received his B.A. degree from Yale in 1886, remaining for an extra year in the Sheffield Scientific School. In 1891, Dr. Alling was graduated from the College of Physicians and Surgeons, Columbia University. Having become interested in ophthalmology, he remained in New York for a year to work under the late Dr. Herman Knapp and began practice in New Haven, in 1893. In 1896, Dr. Alling became lecturer in ophthalmology at the Yale School of Medicine and, in 1902, was made clinical professor, which position he held until 1938.

A man of sterling character, keen mind, and ready wit, Dr. Alling was a skillful operator, a stimulating teacher, and enjoyed a large practice. He was a member of the New York Ophthalmological Society, the American Ophthalmological Society, and a Fellow of the New York Academy of Medicine.

Eugene M. Blake.

WARREN DOUGLAS HORNER
(1890-1948)

Dr. Warren Douglas Horner died on the night of October 22, 1948, in his home following a lingering illness. He was born September 11, 1890, at Klamath Falls, Oregon. After obtaining his preliminary education in Chico, California, he attended the University of California, where he was graduated in 1913. Three years later he received his M.D. degree from the university's medical school. Following this he served his internship at the San Francisco Hospital.

During the first world war, Dr. Horner served as a Navy lieutenant at base hospitals in Scotland and France. Upon discharge from the Navy he devoted one year to special study of the diseases of the eye, ear, nose, and throat at the University of Vienna, following which he entered private practice in 1923. From 1929 on, Dr. Horner limited his practice to the diseases of the eye and was appointed associate clinical professor of ophthalmology of the University of California and chief of ophthalmology of the University of California's Section of Ophthalmology at San Francisco Hospital.

Immediately after the attack on Pearl Harbor, Dr. Horner was recalled to active duty in the Navy with the rank of captain and was finally stationed at Oak Knoll Hospital, where he was retired in 1945.

He contributed numerous important articles to the ophthalmic literature, the most outstanding one being his thesis for the American Ophthalmological Society entitled, "A study of dinitrophenol and its relation to cataract formation."

Dr. Horner was honored by his colleagues on numerous occasions serving as chairman of the eye sections of the county and state societies. He was the first president of the San Francisco Ophthalmological Round Table, and was vice chairman of the Section on Ophthalmology of the American Medical Association at its centennial celebration in Atlantic City in 1947.

In addition to his appointment to various San Francisco hospitals, he was ophthalmic surgeon and consultant at the United States Marine Hospital of San Francisco.

Dr. Horner was a member of the San Francisco County Medical Society, the California Medical Association, the American Medical Association, the American Academy of Ophthalmology and Otolaryngology, the American Ophthalmological Society, the Association for Research in Ophthalmology, the San Francisco Round Table, and the Pacific Coast Oto-Ophthalmological Society.

On June 28, 1919, he was married to Madge Clendenin. To this happy marriage with its beautiful home life were born a

daughter, Mrs. Harold A. Hyde, and a son, Douglas C. Horner.

Aside from his practice, Dr. Horner's chief interest was in his work with the students and residents. Persistence and attention to detail were primary virtues that he tried to instill in his associates. He was a good teacher, and gave freely of his time in this field. He was devoted to his work, and was an intelligent observer and a skillful operator.

Dr. Horner was tall, handsome, friendly, with a modest personality and a keen sense of humor, and was always ready with a clever story. His charm, graciousness, and love of people gained for him a host of friends within and outside his profession. To his friends he was known as "Bud," and because he was so real and so gracious he is remembered by thousands of friends, patients, and students.

Frederick C. Cordes.

BOOK REVIEWS

CORNEAL GRAFTS (keratoplasties) (Les Greffes de la Cornée). By L. Paufique, G. P. Sourdille, and G. Offret. Published under the auspices of the French Society of Ophthalmology. Paris, Masson et Cie, 1948. 359 pages, 135 figures, 20 plates, 4 of which are in color, bibliography. Price, not listed.

The authors have succeeded in giving us a well-illustrated, factual description of corneal grafting in all of its manifestations from history, instrumentation, and the various techniques to a discussion of the healing and its complications. The indications and contraindications for the operation are clearly set forth. It is gratifying to note the prominence given to American authors in the contributions to this field of ocular surgery.

An analysis of the results of the authors' partial nonperforating keratoplasty operations showed 71 anatomically favorable results out of 90 cases (75 percent) according to the criterion of Filatov, that is, the graft remained transparent, permitting one to see the details of the anterior chamber and the ocular fundus. There were eight poor results. These results are a little better than those obtained from keratectomies.

The book is well printed and is a worthy companion of those hitherto published by the same firm under the auspices of the French Society of Ophthalmology. Ophthalmologists who read French will get much out of it. It is hoped that an English edition may become available.

Derrick Vail.

DA BIOMICROSCOPIA ESTÉROSCÓPICA DO FUNDO DO ÔLHO DO CÃO NA VIGÊNCIA DA HIPERTENSÃO (Experimental stereoscopic Biomicroscopy of the Ocular Fundus of the Dog in the Course of Experimental Hypertension). By Cyro de Barros Rezende. Independently printed monograph, São Paulo, Brazil, 1948. Stiff paper covers, 167 pages, 28 plates, 21 in color, 7 in black and white.

This is the author's thesis presented to the Faculty of Medicine of the University of São Paulo in competition for the chair of professorship of clinical ophthalmology, "approved with distinction." Following to some extent the lines of Goldblatt's work on the same general topic, the author describes (in Portuguese) his modified method of slitlamp study of the ocular fundus of the experimental animals, with ample illustrations of the special apparatus employed, as well as description and illustration of the supplemental apparatus for measuring the arterial pressure of the dogs. Goldmann's contact lens was successfully applied to this study.

The beautiful color drawings, under the slitlamp, of the tapetum lucidum and nigrum in normal animals and in the course of the hypertensive studies were made by Professor Rezende's São Paulo colleague, Dr. A. G. Silva. There are also five excellent photomicrographs of retinal changes.

Interference with the circulation of the

kidney in the 24 experimental dogs was accomplished by clamping the retinal artery with Goldblatt's silver forceps.

The author states the following conclusions: Of all the ocular changes in benign experimental hypertension of the dog, the first and most constant is superficial edema of the retina. This is chiefly located in the tapetum nigrum and was most frequently evident in those retinal areas traversed by the large vessels. Even in the incipient edemas, the light bundle of the slitlamp showed slight elevation of the internal limiting membrane of the retina. As the edema became more intense, the retina lost its transparency and became grayish white. These appearances were confirmed in microscopic sections. In the benign experimental stage there was also accentuation of the median reflexes of the retinal arteries, with sheathing of the vessels and compression at the arteriovenous crossings. Changes encountered in malignant experimental hypertension included one instance of intense intraocular hemorrhage, white patches with fluffy margins, papillary edema, and marked lateral tortuosity of the retinal arteries. (List of 72 references.)

RÉPERCUSSIONS SUR L'ENFANT DES MALADIES INFECTIEUSES DE LA MÈRE PENDANT LA GROSSESSE. By F. Bamatter. Basel and New York. S. Karger, 1949. 60 pages, 24 figures. Price, 7.50 francs.

In this excellent monograph the author discusses, in general, the exogenous factor in the fetal dysgeneses and the placental transmission of maternal infections. A full-page table lists the bacteria, viruses, protozoans, and helminthes, the placental transmission of which has been demonstrated in man and in animals.

After a very brief statement of the known facts of the transmission of syphilis, tuberculosis, infectious icterus, paratyphus, and malaria, monographic treatment is accorded

toxoplasmosis and the embryopathy of rubella.

A tabulation makes all the important clinical and pathologic data perspicuous. Excellent halftones illustrate the monograph, two of which are particularly illuminating. In one, the sites of localization of toxoplasmosis are indicated on a drawing of a fetus together with brief statements on mode of infection. In the other the tissues which may be injured by maternal rubella are indicated on a model of a 4-mm. (one-month) human fetus.

F. H. Haessler.

BULLETIN SOCIÉTÉ BELGE D'OPHTALMOLOGIE. Number 89, 1948.

In the minutes of the meeting of June 20, 1948, is a discussion of the eye signs preceding death. In speaking of retrobulbar injection, one author says that he uses a 5-cm. needle and injects 1.5 cc. of novocain-adrenalin (4 percent) solution.

Van Lint discusses the role of pressure on the globe in intracapsular cataract extraction and explains his technique which includes a conjunctival flap, keratome and scissors section, total iridectomy, and removal of the lens by suction, coupled with pressure from below toward the center of the globe with an Arruga expressor.

A case of total ossification of the choroid following an injury 60 years before is presented.

Of the two instruments discussed, one is for the removal of foreign bodies from the cornea and the other is a shadow-casting device to be used with the biomicroscope.

Among the case reports are a case of parenchymatous keratitis with keratoplasty resulting in a final vision of 0.1; two cases of Groenouw's disease of the cornea; and one of hypercalcemia and corneal calcifications.

Ophthalmoscopic manifestations of myasthenia gravis are discussed, and photographs

are shown of the patient before and after the injection of prostigmin.

Three cases of gargoylism are presented. Three cases of keratoconjunctivitis sicca are mentioned, with various treatments, including closure of the tear points, section of the sympathetic nerves, irradiation of the lacrimal gland, injections of pilocarpine and prostigmin, installation of gelatin drops of Gifford, vitamin-B_2 therapy, and male-hormone therapy.

There is a gonioscopic picture of a case of acute iridocyclitis. Two cases of acute glaucoma which followed the subconjunctival injection of adrenalin for the treatment of iritis are described. Treatment of four cases of optic neuritis are discussed. Intraarachnoid injections of penicillin were given.

There is a discussion of therapeutic tissue implants in the treatment of retinitis pigmentosa. Among the ocular manifestations in one case of this disease were irregular distribution of the cutaneous pigment, light perception only, convergent strabismus, nystagmus, atrophic globes, seclusion of the pupil, miosis, and hypotony of each eye. It is stated that only 11 comparable cases have been reported in the literature. It is a congenital syndrome.

Two cases of retinal tears without detachment are discussed.

Bennett W. Muir.

———

TRANSACTIONS OF THE OPHTHALMOLOGICAL SOCIETY OF PARIS (and of the Ophthalmological Societies of the East, of Lyon, and of the West). Meeting of June, 1948, pp. 242-328; meeting of July, 1948, pp. 334-401.

Mme. Nada Matavulj reported her observations on the tissue therapy of Filatov. In spite of the short time of this study (3 years), it seems to be clear that the biogenic stimulation in the form of placenta, placental extract, aloes, and cod-liver oil gave unexpected improvement in otherwise hopeless cases.

François Pierre reported on three children with retrolental fibroplasia. He describes the clinical appearance and differential diagnosis and stresses the fact that this anomaly was described in France in 1883 by Vassaux.

Delthil, Halbron, and Navdin describe two cases of postsurgical aniridia which they do not consider to be as critical an accident as is generally believed.

Thurel doubts the importance of opticochiasmal arachnoiditis but considers the blocking of the pericerebral arachnoidal spaces of influence because it causes the resorption of air over the hemispheres and accumulation of cerebrospinal fluid and, with it, distention of the cisterna basalis.

Bonnet found that the fundus pictures of amaurotic idiocy in a child with craniofacial dysostosis suggested that this latter condition might be not only a malformation and premature closure of the facial sutures but also a degeneration of the cerebrum and the retina.

In the July issue is an interesting and concise paper on the heterophorias, as delivered by Suzanne Braun-Vallon at the November, 1948, meeting of the French Society of Ophthalmology. The fundamental principles and clinical applications are adequately presented in six chapters, with 11 figures, charts, and a bibliography.

Alice R. Deutsch.

ABSTRACT DEPARTMENT

Abstracts are classified under the divisions listed below. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

1. Anatomy, embryology, and comparative ophthalmology
2. General pathology, bacteriology, immunology
3. Vegetative physiology, biochemistry, pharmacology, toxicology
4. Physiologic optics, refraction, color vision
5. Diagnosis and therapy
6. Ocular motility
7. Conjunctiva, cornea, sclera
8. Uvea, sympathetic disease, aqueous
9. Glaucoma and ocular tension
10. Crystalline lens
11. Retina and vitreous
12. Optic nerve and chiasm
13. Neuro-ophthalmology
14. Eyeball, orbit, sinuses
15. Eyelids, lacrimal apparatus
16. Tumors
17. Injuries
18. Systemic disease and parasites
19. Congenital deformities, heredity
20. Hygiene, sociology, education, and history

2

GENERAL PATHOLOGY, BACTERIOLOGY, IMMUNOLOGY

Bodian, M. An aid in detecting trachoma-like inclusion bodies in the conjunctiva. Arch. Ophth. 40:147-151, Aug., 1948.

The inclusion bodies are observed in the conjunctival scrapings in cases of trachoma, inclusion conjunctivitis, psittacosis and lymphogranuloma venereum. A red light obtained by using the E light red photographic filter (Wratten), series 23A, over the light source, increases the visibility of the bodies in slides stained by the Giemsa method. John C. Long.

Samuels, B. Necrosis of intraocular tissues. Arch. Ophth. 40:101-120, Aug., 1948.

Noninflammatory necrosis is caused by circulatory disturbances and may follow iridodialysis, cyclodialysis and glaucoma. Inflammatory necrosis may be caused by pyogenic bacteria in the cornea, anterior chamber or vitreous. Necrosis caused by trauma and by neuropathy and degeneration of malignant melanomas is described in detail. Artificially induced necrosis may follow radiation therapy for retinoblastomas and diathermy treatment of retinal detachment. (10 figures.) John C. Long.

Weiss, C., Shevky, M. C., and Perry, I. H. Experimental investigation of the pathogenicity of diphtheroids isolated from the human conjunctiva. Arch. Ophth. 40:23-38, July, 1948.

The first attempt to establish an etiologic relation between a diphtheroid and a disease of the eye occurred in 1879, when Italian investigators isolated Corynebacterium xerose during the course of an institutional epidemic of xerophthalmia. Later, in 1883, German workers demonstrated the presence of diphtheroids on the conjunctiva of patients with a nutritional deficiency but it was soon realized that these bacteria are usually present on normal and inflamed conjunctivas and other surfaces of the body. In general, corynebacteria are non-motile, grampositive, aerobic, nonsporulating rods, which resemble Corynebacterium diphtheriae, and usually show uneven staining and variable morphologic changes during growth. When mucin, which occurs in the conjunctiva and other mucous membranes, is used as a vehicle in which to suspend certain bacteria, the

organisms may acquire an increase in virulence for experimental animals. Mucin functions as a protective capsule for the micro-organisms, decreases phagocytosis and intracellular digestion of bacteria and reduces the bacteriolytic power of serums.

Diphtheroids, resembling C. xerose, which were isolated from the human conjunctiva, grew well in a menstruum of mucin. When suspended in this medium and inoculated into the anterior chamber of the eyes of albino rabbits, cultures retained their viability in vivo for several days, while in suspensions in saline solution they were rapidly destroyed. Intraocular injection of diphtheroids suspended in saline solution produced moderate inflammation of the ciliary process in albino rabbits. When suspended in mucin, the reaction lasted longer, was much severer and was associated with acute keratitis.

It may be concluded that diphtheroids, which are almost constantly present on the normal and inflamed human conjunctiva, may be potential pathogens.

VEGETATIVE PHYSIOLOGY, BIO-CHEMISTRY, PHARMACOLOGY, TOXICOLOGY

Bonavolontà, G. **Microspectroscopic observations on the living eye.** Ann. di ottal. e clin. ocul. 74:339-349, May, 1948.

In making his microspectroscopic observations Bonavolontà used a Gullstrand slitlamp fitted with Abbe's spectral eyepiece and with an arc light in place of the usual Nitra lamp. Conjunctiva, cornea, aqueous, and vitreous have a uniform continuous chromatic spectrum, without distinguishing peculiarities, but may present the characteristic spectrum of oxyhemoglobin in the presence of circulating or extravasated blood. The spectrum of the normal crystalline lens is shortened toward the red end (it does not extend

beyond 620 to 630 μμ., whereas the spectrum of the conjunctiva extends to 660 or 670 μμ.) and is relatively dim toward the violet end. These characteristics of the lenticular spectrum disappear as the lens becomes cataractous, so that the spectrum of a mature cataract is normal as regards extension and brightness. Spectroscopy affords a means of differentiating between hemorrhagic and inflammatory exudates in the vitreous.   Harry K. Messenger.

Brolin, S. E. **Spectrometric, photoelectric determination of the fluorescence of the eye lens. A quantitative and objective method for experimental investigations.** Acta ophth. 26:395-411, 1948.

During certain pathologic conditions of the lens fluorescence undergoes significant changes, and it is possible that fluorescence may be a sensitive indicator of metabolic changes in the lens. The author describes a method of spectrometric determination of the intensity of lens fluorescence, which is accurate enough for experimental investigation. The fluorescent light from a lens preparation in a quartz tube is analyzed with a spectrograph and an electron multiplicator photocell. The data can be recorded objectively, and small changes in the fluorescence of the lens can be recognized spectrometrically. There is a difference in the intensity and spectral localization between the cortex and the nucleus.

Ray K. Daily.

Davson, H. **Some considerations on the salt content of fresh and old ox corneae.** Brit. J. Ophth. 33:175-182, March, 1949.

The eyes from freshly killed oxen were examined, immediately and after 24 hours of ice storage, for sodium, potassium, chloride and water content of the cornea and of the aqueous humor. After 24 hours the cornea had an increase of water content, a slight decrease in sodium and a slight increase of potassium and chloride.

There was a corresponding decrease in the concentration of ions in the aqueous which suggests that the increased hydration represents a migration of aqueous into the cornea and not a mere osmotic drainage of water from this fluid.

Morris Kaplan.

Feldman, J. B. **Mydriatics.** Arch. Ophth. 41:42-49, Jan., 1949.

This paper evaluates the clinical merit of the commonly available mydriatics as to such factors as safety, speed of action and return to normal pupillary size. In this study 12 mydriatics were checked. Ordinarily, they worked more efficiently on cloudy days and on patients with blue eyes. Homatropine hydrobromide, 1 percent, atropine methylnitrate, 1 percent, and dibutoline sulfate, 5 percent, dilated the pupil in the greatest number of patients. Dibutoline sulfate, 5 percent, gave definite cycloplegia in association with mydriasis in the greatest number of patients.

Paredrine hydrobromide was less potent but was quite satisfactory as a mydriatic in a number of cases. Glaucoma is indeed a rare complication of mydriasis. Even when a mydriatic has been mistakenly used in "pre-glaucoma" one will obviate disaster by keeping the patient until the pupil has contracted particularly since much more powerful miotics than 1-percent pilocarpine hydrochloride are available. Ralph W. Danielson.

Jaffe, N. S. **Cholinesterase in the aqueous of the eye.** Arch. Ophth. 40:273-278, Sept., 1948.

Theoretically, there can be only faint traces of cholinesterase in the normal aqueous, since the enzyme is a protein. Aqueous from the eyes of 10 normal cats showed no cholinesterase, or insignificant traces of it. The first and second aqueous after paracentesis showed marked cholinesterase activity; the amount is pro-

portionate to the plasma protein in the aqueous. Ralph W. Danielson.

Jaffe, N. S. **Practical application of the denervated iris.** Arch. Ophth. 40:317-325, Sept., 1948.

The denervated iris, of the cat is too sensitive an indicator of the epinephrine content of foreign solutions, but may be used as a very sensitive indicator of the increase in the epinephrine level of the blood. In the stage of excitement of ether anesthesia the output of the epinephrine in eight cats was so great that it remained for an hour. Ether is sympathomimetic. Barbiturates inhibit the production of epinephrine due to ether anesthesia. Ralph W. Danielson.

Lehrfeld, L., and Donnelly, E. J. **Contaminated ophthalmic ointments.** Arch. Ophth. 40:39-45, July, 1948.

The unused tube of ointment was in most instances sterile, whereas the used tubes were frequently contaminated. The observations in this study call for a revaluation of the use of ophthalmic ointments in the eye after operation and of the use of ointments for ophthalmic conditions in general. The authors have no proof that infections actually occur from the use of contaminated ointments, nor that the organisms found in the contamination were pathogenic bacteria but even sulfathiazole ointment and penicillin ointment may become contaminated before the contents of the tube are exhausted.

Ralph W. Danielson.

von Sallmann, L. **Controversial points in penicillin therapy of ocular diseases.** Arch. Ophth. 39:752-804, June, 1948.

This is a comprehensive report based largely on detailed experimental studies of the use of penicillin in the eye. The parenteral us of the drug is investigated from the standpoint of the passage of penicillin across blood aqueous barrier,

penicillin levels in ocular fluids after ligation of the renal vessels and the passage of penicillin into the ocular fluids in ocular inflammation. The surface application of penicillin by means of solutions, ointments, and iontophoresis is studied. Studies are described of the injection of the drug into the conjunctiva, anterior chamber, lens, and the vitreous.

The best results from the systemic administration of penicillin in severe ocular infections are obtained by the administration of massive doses in the acute phase, aided by the simultaneous local instillation of vasodilators in less violent inflammations. The continuance of penicillin activity was usually observed in the tears for eight hours after one instillation of drops or ointment. The rather involved factors concerned in iontophoresis are discussed. With observance of specifically outlined requirements, direct injection of penicillin into the vitreous can be considered at present the most reasonable treatment of infections of the posterior segment. The many points revealed by this searching investigation should be of great value in the practical application of penicillin therapy in eye infections.

John C. Long.

von Sallmann, L., and Moore, D. H. Electrophoretic patterns of concentrated aqueous humor of rabbit, cattle and horse. Arch. Ophth. 40:279-284, Sept., 1948.

Information about the effects on the eye of the drugs, which are usually administered locally, when they are administered systemically in their usual dosage, is limited.

In experiments the authors found that morphine sulfate administered intramuscularly in doses ranging from 8 to 18 mg. produced pupillary constriction, increase in accommodative power and decrease in ocular tension in normal eyes. Morphine produced similar effects in glaucomatous eyes; in none of the 14 eyes studied did

its use lead to an increase in intraocular pressure. In equivalent doses, atropine, given intramuscularly, produced much less pupillary dilation and weakening of accommodation than did scopolamine. Neostigmine, in a dose which produced definite increase in intestinal peristalsis, had no consistent ocular effects.

Schlosshardt, H., and Adam, W. The penicillin content of the aqueous after intramuscular, intravenous and local penicillin. Klin. Monatsbl. f. Augenh. 113:333-342, 1948.

The results, which were all obtained in animal experiments, correspond to those found in the American literature. (References.) Max Hirschfelder.

Theodore, F. H. Use of propionates in ophthalmology. Arch. Ophth. 41:83-94, Jan., 1949.

The purpose of this paper is to acquaint ophthalmologists with a group of physiologic antibiotics, which have hitherto not been used in treatment of ocular infections, and which have certain advantages over medicaments now in general use. The group consists of the lower fatty acids which occur in the human body. In this preliminary report the sodium salt of one of these fatty acids, sodium propionate, was selected for study. The lower fatty acids are nontoxic, physiologic antibiotics and fungicides. Sodium propionate, a fatty acid derivative, was used clinically in about 400 cases of conjunctivitis, blepharitis, and keratitis. It has proved efficacious and nonirritating, especially in treatment of chronic conditions. Ralph W. Danielson.

Woods, A. C., and Burky, E. L. Studies in experimental ocular tuberculosis. Arch. Ophth. 39:471-490, April, 1948.

The authors report on the experimental

results in the therapy of ocular tuberculosis in immune-allergic rabbits using two sulphones, "promin" and "promizone," as the therapeutic agents. Both of these agents exert a deterrent action on the course of the ocular tuberculosis. The action becomes evident after the third week of treatment. The action of the two drugs is about the same.

Histologic evidences of tuberculous disease persist in the majority of the eyes of the treated animals. The lesions, however, are fewer and are less severe than in the control eyes. In transfer experiments with the extract of the uveal tract from the eyes of the seven treated animals only one positive result was obtained. All of the control eyes gave positive transfers. These results may be due either to a degradation of the virulence of the organisms, allowing the resistance of the host to become effective, or to a direct bactericidal action.　　John C. Long.

Woods, A. C., and Burky, E. L. **Studies in experimental ocular tuberculosis.** Arch. Ophth. 40:1-13, July, 1948.

In a previous study of the effect of treatment with two sulfone compounds, "promin" and "promizole," on experimental ocular tuberculosis in the immune-allergic rabbit, it was not clear whether the deterrent action of the sulfone compounds noted was due to a bactericidal action or to degradation or attenuation of the virulence of the organisms, thus allowing the resistance of the host to become more effective. The experiments here reported were undertaken to clarify this point. "Promin" and "promizole" used in the same dose as that which had a pronounced deterrent effect on ocular tuberculosis in the immune-allergic rabbit were only slightly deterrent on ocular tuberculosis in animals that had not been sensitized. These drugs probably have a limited bactericidal effect on the tubercle bacillus.　　Ralph W. Danielson.

Woods, A. C., and Wood, R. M. **Studies in experimental ocular tuberculosis: XII. Effect of streptomycin and "promizole" on experimental ocular tuberculosis in the immune-allergic rabbit.** Arch. Ophth. 40: 413-432, Oct., 1948.

Streptomycin exerted a deterrent action on the course of ocular tuberculosis produced by inoculation of the eyes of immune-allergic rabbits. Despite the absence of clinical evidence of activity, histologic examination of the eyes showed minimal to moderate activity and transmission experiments and cultures showed that the tubercle bacillus was still alive in some of the eyes. A combination of streptomycin and "promizole" produced a more dramatic response. After four weeks of combined treatment, the diseased eyes were clinically and histologically inactive and transmission experiments were negative in more of the animals. Streptomycin has a definite bacteriostatic and a partial bactericidal action on the tubercle bacillus in ocular tuberculosis. The combination of streptomycin and "promizole" is somewhat greater than would be expected from a summation of their individual actions.　　John C. Long.

PHYSIOLOGIC OPTICS, REFRACTION, COLOR VISION

Auerswald, W. **The area effect in scotopic vision.** Ophthalmologica 117:104-109, Feb., 1949.

For threshold stimuli there is a fairly simple mathematical relationship between intensity and duration of the stimulus as long as the portion of stimulated retina is kept small. Stimulation of larger retinal areas introduces a new factor, the so-called area effect. The occurrence or non-occurrence of the area effect seems to depend more upon the location than upon the total number of the stimulated retinal elements.　　Peter C. Kronfeld.

Balcet, A. **Myopia from the manufacture of woolen goods.** Rassegna ital. d'ottal., 17:379-383, Nov.-Dec., 1948.

In a group of forty-two women workers, ranging from 16 to 19 years of age, only nine were emmetropic. The others had two to five diopters of myopia. The writer ascribes the myopia to the nature and conditions of their work, which is very exacting, is done at close range and in poor light.   E. M. Blake.

Berger, Curt. **Some experiments on the width of symbols as determinant of legibility.** Acta ophth. 26:517-569, 1948.

The purpose of this study was to determine the effect of a change in the width of symbols on their legibility. An important interaction takes place between all factors affecting legibility, such as form, width and height. This study is a part of a long-range statistical program which will emphasize the effect of interaction between the factors.

The graphic data show that the increased width of the letters results in an increased legibility which is explained as a purely retinal function, namely the resolution threshold of the fovea centralis. (19 graphs.)   Ray K. Daily.

Best, F. **Embryologic considerations in the origin of the lateral inversion of the optic pathways in the brain.** Klin. Monatsbl. f. Augenh. 113:234-246, 1948.

Best provides a critical review and an extension of the theories of Cajal.
                Max Hirschfelder.

Bottoni, Angelo. **The light sense, and the various methods of measuring it in clinical practice.** Ann. di ottal. e clin. ocul. 74:396-420, June, 1948.

This article is a monograph on the light sense and its measurement and is illustrated with diagrams of various adaptometers and other devices. Bottoni finds adaptometry clinically useful in the detection and measurement of vitamin A deficiency, in studying the role of vitamin A in community and racial health, and in the detection and treatment of night blindness in night workers.
                Harry K. Messenger.

Casanovas, José. **Chalazion and astigmatism.** Arch. Soc. oftal. hispano-am. 9: 23-27, Jan., 1949.

Transient astigmatism may be caused by a chalazion, and glasses prescribed before its extirpation may be unsuitable afterwards.   Ray K. Daily.

ten Doesschate, J. **The relationship between the extrafoveal scotopic threshold and the distribution of retinal rods.** Ophthalmologica 117:110-115, Feb., 1949.

This is another quantitative study of the relationship between visual function and the number of visual elements per mm.^{2} of stimulated retina. The histologic basis for most of the recent work in this field was furnished by Østerberg who reported the results of careful visual cell counts in the eye of a 16-year-old boy. Crozier and Holway compared these results with their own determinations of the extrafoveal absolute scotopic threshold of the light sense and found no simple relation between the two sets of data. Now ten Doesschate compares Østerberg's rod counts in the horizontal retinal meridian with the scotopic light threshold determinations of Stiles and Crawford and finds *good agreement between the histologic and the visual data. The existing minor discrepancies can easily be explained by individual variations and other causes.* These results strongly support the theory —already firmly established—that the cones and rods form the anatomical substrata of the photopic and scotopic mechanism, respectively. Peter C. Kronfeld.

Hardy, L. H., Rand, G., and Rittler, M. C. **Incidence of defective color vision among psychotic patients.** Arch. Ophth. 40:121-133, Aug., 1948.

A high incidence of defective color vision in psychotic patients has been reported but the authors found that the incidence of color blindness in the 235 psychotic patients tested with pseudo-isochromatic plates was not significantly higher than that in the normal population.

John C. Long.

Henderson, J. W. **Cotton sutures in ophthalmic surgery.** Arch. Ophth. 39:545-548, April, 1948.

Cotton fiber is an inert material with a natural twist which can be tied into small, stabile knots with a high tensile strength. It incites early healing with little undesirable tissue response. These characteristics are features that might be considered in the possible use of cotton as a suture material in ophthalmic surgery. The author illustrates the use of cotton sutures in a considerable variety of ophthalmic operations. John C. Long.

Kinsey, V. E. **Spectral transmission of the eye to ultraviolet radiations.** Arch. Ophth. 39:508-513, April, 1948.

The ultraviolet absorption spectrums of various components of the albino rabbit eye have been measured. The limit of transmission for the whole eye is approximately 330 millimicrons; for the lens, 310, and for the aqueous and the vitreous and cornea, separately, approximately 280 millimicrons. In the corneal epithelium the chief absorbing element is nucleoprotein; its limit of transmission is less than 230 millimicrons. The amount of radiant energy from the sun to which the eye would have to be exposed before minimal damage occurs in the lens is calculated to be about three times the dose necessary to produce minimal damage to the cornea. So little ultraviolet radiation reaches the retina that damage would be extremely unlikely.

John C. Long.

Kugelberg, I. **On the effectiveness of tabulæ pseudoisochromaticæ B. K.** Acta ophth. 26:429-437, 1948.

This is an evaluation of pseudoisochromatic tables published in Sweden. Color plates are of little value in differentiating protanomolous and deuteranomolous vision of moderate severity, and complicated figures may cause difficulties for persons with normal color vision.

Ray K. Daily.

Macnie, J. P. **Clinical aniseikonia.** Arch. Ophth. 40:326-331, Sept., 1948.

A study was made of the 1,027 patients examined for aniseikonia at the Institute of Ophthalmology of the Presbyterian Hospital, New York, between December, 1936, and December, 1941. Aniseikonia was demonstrable in 527 and 463 received glasses. Of the latter, 365 (79 percent) were relieved of all or a part of their symptoms, and 98 (21 percent) were not benefited. In 1946, from five to ten years later, a questionnaire revealed that of 304 patients, one half were benefited. No symptoms are characteristic of aniseikonia, but symptoms associated with use of the eyes not relieved by the usual ophthalmic therapeutic measures may be due to it. The presence of aniseikonia cannot be anticipated on the basis of anisometropia or the magnitude of the refractive error. Nor is it possible to anticipate whether the correction of aniseikonia will aid the patient. Ralph W. Danielson.

Nolasco, J. B., and Rodil, D. **Responses to the Ishihara test for color perception.** Arch. Ophth. 41:20-23, Jan., 1949.

Approximately 2,000 male and female Filipino students were tested with the Ishihara color plates. The incidence of defective color vision in men was 4.3 percent; in women 0.3 or 0.2 percent, depending on which criterion was used.

Ralph W. Danielson.

Pascal, J. I. The "incident neutral" point in retinoscopy. Arch. Ophth. 39: 550-551, April, 1948.

The point where the emergent rays from the patient's eye meet is ordinarily spoken of as the neutral point. There is another neutral point which concerns the incident light and may be called the "incident neutral" point. This point is obtained when one uses a concave mirror and the incident light is made to focus in the plane of the patient's pupil. There will then be neutrality of motion irrespective of any refractive error the patient may have.   John C. Long.

Pascal, J. I. Real significance of centering a contact lens. Arch. Ophth. 39:514-516, April, 1948.

The prevailing method among physicians when centering a contact lens has been to center the cornea of the lens with the cornea of the eye. To get the best optical effect of the contact lens its cornea should be centered with the crystalline lens. Objectively this is impossible, but subjectively it can be done by observing the effect on vision of slight displacement of the position of the contact lens. Theoretical considerations of the variations in optic axis produced by contact lenses are discussed.   John C. Long.

Paton, R. T. Eye ointment dispenser. Arch. Ophth. 39:549-550, April, 1948.

A metal container is described into which the standard ointment tube is inserted. Only the tip of the sterilizable container comes in contact with the eye. (1 figure)   John C. Long.

Ríos Sasiain, Manuel. The extrafoveal sensitivity of the retina. Arch. Soc. oftal. hispano-am. 9:147-151, Feb., 1949.

Physiologic nocturnal myopia was utilized for determination of the most sensitive parafoveal area. With a black disk 9 cm. in diameter on a white background, with a controlled illumination, and regulated extrafoveal fixation it was found that the area of greatest scotopic visual acuity is 15 degrees from the fovea. DIAGNOSIS AND THERAPY

Benton, C. D., Jr., and Heyman, A. Treatment of ocular syphilis with penicillin. Arch. Ophth. 40:302-310, Sept., 1948.

During the past three years the authors have used penicillin in the treatment of 39 patients with various manifestations of syphilis of the eye. Penicillin produced little or no immediate response in interstitial keratitis but the opacity cleared and the inflammation subsided in three to five months. Good or excellent vision resulted in 80 percent of the eyes treated in the first attack, but penicillin did not always prevent keratitis in the second eye. Penicillin treatment of six patients with acute iritis associated with secondary syphilis healed immediately and vision became normal. Papilledema associated with syphilitic meningitis responded well to penicillin therapy. In four of eight patients with primary optic atrophy the process seemed arrested 11 to 24 months after treatment. Combination with fever therapy is advised for optic atrophy. Ralph W. Danielson.

Cimbal O. The methods of penicillin therapy in eye diseases. Klin. Monatsbl. f. Augenh. 113:342-353, 1948.

The local use of penicillin in diseases of the eye is far superior to general, as only weak concentrations of penicillin reach the corneal tissue and the interior of the eye after intramuscular or intravenous injection except in pyogenous infections of the adnexa. Conjunctivitis may be treated with drops but corneal infections need repeated 15-minute applica-

tions of penicillin, 50,000 to 200,000 units per cc., by means of a cotton applicator. For penicillin therapy of the interior of the eye a cotton tampon with a few drops of 100,000 units per cc. penicillin solution is introduced into the lower conjunctival fornix. This method is preferred when pure crystalline penicillin is not available for subconjunctival injections. (References.) Max Hirschfelder.

Fedrizzi, G., and Ferri, L. Soft-ray roentgentherapy of superficial eye diseases. Boll. d'ocul. 27:697-705, Nov., 1948.

Plesioroentgenotherapy is recommended for practically any inflammatory lesion on the surface of the eye. If the equipment is not available, one may use any roentgen apparatus and apply 30 to 40 r per session until the total dose is 180 to 320 r. A short review of 31 corneal and scleral lesions shows that in some cases a satisfactory result can be obtained.

Fiore, Tito. Pentothal anesthesia in ocular surgery. Ann. di ottal. e clin. ocul. 74:381-395, June, 1948.

Pentothal anesthesia is preferable to inhalation anesthesia and is particularly indicated in the treatment of injuries to the globe, in acute glaucoma, in operations on the adnexa, and in enucleation and exenteration and other destructive operations. Administered by rectum it is the anesthesia of choice in operations on children.

Harry K. Messenger.

Gardilčić, A. The use of rat tail tendons as suture material in ophthalmology. Ophthalmologica 117:115-126, Feb., 1949.

As reported earlier by K. Pischel, rat tail tendons make satisfactory absorbable material for corneoscleral sutures. The author describes a convenient method of obtaining and preparing the tendon and reports experimental studies with various suture materials imbedded intracorneally

in rabbits. Rat tail tendon is better tolerated than catgut, silk or human hair.

Peter C. Kronfeld.

Gifford, H. **Motor block of extraocular muscles by deep orbital injection.** Arch. Ophth. 41:5-19, Jan., 1949.

In order to get more complete motor anesthesia and lower vitreous pressure, the author has (after considerable experimental work and cadaver dissections) devised an altered technique in retrobulbar injections which he describes in detail. Using 2 cc. of 2 or 4-percent procaine hydrochloride, with 0.4 cc. of epinephrine hydrochloride to the ounce (29 cc.), he was able to produce a better than 60-percent motor block in 74 percent of 158 cases.   Ralph W. Danielson.

Grancini, L. E. **Experimental anaphylaxis with normal placenta and with Filatow's preparation.** Rassegna ital. d'ottal. 17:357-366, Nov.-Dec., 1948.

The writer transplanted placenta under the conjunctiva 30 times in man for various intra-ocular pathological processes according to Filatow's method. Animal experiments demonstrated that the Filatow placental tissue was not anaphylactic when implanted in the peritoneal cavity or in the orbit. Fresh placental tissue, under the same conditions, produced an anaphylactic reaction. Filatow's tissue is not toxic and does not produce anaphylaxis in animals sensitized by fresh placental tissue. The conclusion is reached that the therapeutic results are no better with Filatow's material than with fresh placenta and therefore the latter is preferable.   Eugene M. Blake.

Lindsay-Rea, R. **Eyeball rotating forceps.** Brit. J. Ophth. 33:193, March, 1949.

A locking forceps, whose toothed blades terminate in sharply bent arms, which is used for rotating the eyeball is described.

Morris Kaplan.

McMackin, J. V. **Fixation light.** Arch. Ophth. 40:351-352, Sept., 1948.

In order to simplify the screen test the author has designed a light that can be displayed in the cardinal direction of gaze.

Ralph W. Danielson.

Morano, M., and Franchi, B. **Ocular therapy by low-voltage irradiation at close distances.** Boll. d'ocul. 27:625-638, Oct., 1948.

Low-voltage irradiation at close distance in corneal diseases was beneficial and the authors used the same treatment for diseases of the inner coats. They used a Goral-Siama apparatus, Chaoul type, and a 3-mm. celluloid plate to protect the surrounding ocular tissues from secondary radiation. Usually the dose was 160 to 165 r for uveal, and 190 to 195 r for deeper lesions, using 55 kV, 5 mA, focal distance 5, and the celluloid filter on alternating days for 5 or 6 applications. (3 figures.)

Ruedemann, A. D. **Beta radiation therapy.** Arch. Ophth. 41:1-4, Jan., 1949.

The author discusses the technique of use of the beta ray application in conjunctival and corneal abnormalities and dermatologic growths of the lid. There is a twofold hazard in the use of radiation therapy: to the patient by overdosage, faulty application or severe reaction, and to the ophthalmologist. Means of avoidance are described.

Ralph W. Danielson.

Urrets Zavalía, Alberto. **The action of diamino-diphenyl-sulfone on the ocular complications of leprosy.** Arch. Soc. oftal hispano-am. 9:160-175, Feb., 1949.

This is a tabulated report of the application of this drug in 25 patients with leprosy. The drug prevents the severe uveal complications of leprosy but mild transient iritis may occur during the course of treatment. It is incapable of checking the evolution of slowly progressive ocular leprous lesions. When the anterior uvea is not involved the drug hastens the absorbtion of corneal infiltrates and brings about the disappearance of the thickened corneal nerves. It cannot arrest the progress of the lesion when the iris and ciliary body are affected.   Ray K. Daily.

~OCULAR MOTILITY

Berg, J. L. **Management of vertical heterophoria of paretic origin.** South. M. J. 42:220-224, March, 1949.

Bielschowsky's four types of vertical heterophoria are reviewed. The symptoms of vertical heterophoria vary from a mild drowsiness after one hour of close work to a marked blepharospasm with a chronic blepharoconjunctivitis. The amount of prism prescribed depends on the patient's occupation and upon the amount of variation in the findings between the heterophoria for near and for distance.

H. C. Weinberg.

Casari, G. F. **Clinicopathogenic importance of heterophoria.** Rassegna ital. d'ottal. 17:389-399, Nov.-Dec., 1948.

Twenty cases of heterophoria of various grades were studied and treated with vasodilators and antispasmodic drugs (nicotine amide and chloride of benzilimidazoline). The results were practically nil and not as good as those reported by Angius who administered acetyl-choline. Orthoptic exercises were more effective.   Eugene M. Blake.

Costenbader, F., Bair, D., and McPhail, A. **Vision in strabismus.** Arch. Ophth. 40: 438-453, Oct., 1948.

Conclusions are presented based on a study of 407 cases of squint. From the considerable data given, several generalizations may be made. Visual acuity can be estimated in the infant by determining the ability in foveal fixation. The greater frequency of amblyopia in patients with strabismus can be predicted from a history of "constant" or "monocular" deviation. While the average age of onset of squint may not be significant, the average duration of squint before treatment is most significant in the production of amblyopia. Amblyopia is more frequent with convergent than with divergent squint, and with mechanical convergent than with accommodative convergent squint, and is least frequent with alternating squint. The incidence of amblyopia increases directly with the degree of hypermetropia or the degree of anisometropia present. Total occlusion is the treatment of choice for amblyopia ex anopsia. Helpful suggestions for carrying out the occlusion are given.

Bunge, E. Keratoconjunctivitis epidemica found in lower Silesia in 1944. Klin. Monatsbl. f. Augenh. 113:369-376, 1948.

The author observed a form of keratitis superficialis punctata which probably belongs to the form of epidemic keratoconjunctivitis observed in 1938.
                              Max Hirschfelder.

Citterio, M. Two cases of metastatic furunculiform episcleritis. Boll. d'ocul. 27: 666-672, Oct., 1948.

Two mature women developed metastatic episcleritis a few weeks after infected intragluteal injections. Similar cases have been reported; their significance is the evidence of a generalized metastatic disease, possibly dangerous to the life of the patient. K. W. Ascher.

Corrado, A., and Toselli, C. Metastatic scleral abscess. Rassegna ital. d'ottal. 17: 367-378, Nov.-Dec., 1948.

All recorded instances of metastatic scleral abscess since 1881 are reviewed and abstracted. A 76-year-old man had a generalized furunculosis that had originated in the scrotum. These lesions cleared but several months later there was pain in the left eye and swelling of the lids, considerable exophthalmos, reduction of motility, chemosis with loss of corneal epithelium and a turbid aqueous. The fundus reflex was lacking. Spontaneous rupture of the abscess occurred and eventually the eye was enucleated. Six months later the other eye had an avascular keratitis punctata with absence of pupillary reaction and furuncles of the external auditory canal with staphylococcus.   Eugene M. Blake.

Ellman, P., and Weber, F. P. Sjögren's syndrome. Brit. M. J. pp. 304-305, Feb. 19, 1949.

A case of Sjögren's syndrome is presented in which the respiratory tract was involved.   Irwin E. Gaynon.

Friede, Reinhard. Medical and surgical therapy of serpigenous corneal ulcer. Acta ophth. 26:509-516, 1948.

The author applies alcoholic solutions of bacteriostatics directly to the ulcer after preliminary cocainization; the alcohol causes a flow of fluid until it is neutralized in the tissues, and the stasis about the ulcer is thus relieved. The application is made eight times daily, and

the bacteriostatic is rubbed into and under the ulcer; the necrotic tissue is wiped away. The scars following this treatment are thinner than those after caustics or cautery.

When medical treatment does not stop the progress of the ulcer, the author removes the entire area down to Descemet's membrane with a large trephine. If the floor of the trephine area is clean it may be grafted with a piece of clear cornea; if it is infected the regeneration of the parenchyma is left to itself. When the entire cornea is involved a total keratoplasty will prevent an iris prolapse, with adherent leucoma, staphyloma, and secondary glaucoma. It results in an opaque cornea, which may be dealt with subsequently by further keratoplasties.

Goldsmith, J. **Deep keratitis associated with atypical lichen planus.** Arch. Ophth. 40:138-146, Aug., 1948.

Deep keratitis in a soldier with atypical lichen planus associated with alopecia areata, poliosis, vitiligo and hyper-pigmentation is described. The cornea was not vascularized and the keratitis finally underwent complete regression. The patient had received 55 grams of quinacrine ("atabrine") for malaria. It is thought that quinacrine, as a sensitizing agent, and toxic products of the destructive cutaneous lesions, were probably responsible for the development of the keratitis. John C. Long.

Grom, Edward. **Limbal intrascleral cyst.** Ann. d'ocul. 182:52-56, Jan., 1949.

A six-year-old child, struck in the left eye by an arrow six years before, developed a cyst at the limbus. The eye was enucleated because of degeneration and pain. The cyst contained conjunctival epithelium and the walls were formed by sclera which had undergone hyalin degeneration. Chas. A. Bahn.

Rados, A. **Conical cornea and mongolism.** Arch. Ophth. 40:454-478, Oct., 1948.

The author has recently observed two cases of bilateral conical cornea associated with mongolism. The clinical characteristics of mongolism and the reported associated eye abnormalities are described in detail and the extensive literature on the etiology of mongolism is reviewed. The etiology of conical cornea is discussed from the standpoint of its association with vernal conjunctivitis, and with various endocrine and hereditary factors. It is possible that conical cornea may arise from endocrine abnormalities, particularly when associated with mongolism. John C. Long.

Redl, T. **Treatment of ophthalmia neonatorum at the University Eye Clinic in Vienna.** Klin. Monatsbl. f. Augenh. 113: 353-362, 1948.

The results of penicillin therapy in 37 cases are tabulated. The solutions ranged from 250 to 1,000 units per cc. and drops were used at 10-minute intervals from 3 to 12 hours. In all but five a culture was negative within four to ten hours. The author had the impression that a 1,000-unit solution is irrating and that a 500-unit solution used for 12 hours promises the best results with the least chance of recurrences. Max Hirschfelder.

Roggenkaemper. **Treatment of keratoconjunctivitis nummularis with ether.** Klin. Monatsbl. f. Augenh. 113:377-378, 1948.

The author drops 4 to 6 drops of ether on the anesthetized cornea in keratoconjunctivitis epidemica. Atropine and bandage follows this procedure. The eyes became well in six days, one third of them without any scars. Max Hirschfelder.

Rosen, E. **Interstitial keratitis and vestibuloauditory symptoms following**

vaccination. Arch. Ophth. 41:24-31, Jan., 1949.

The report by Cogan of the syndrome of nonsyphilitic interstitial keratitis and vestibuloauditory symptoms of unknown etiology has stimulated interest in this subject. Because of a suggested etiologic factor in the case reported, this paper is submitted as an introductory study of postvaccinial encephalitis. In a review of Cogan's four cases Mogan and Baumgartner's case, and the one reported present case, certain clinical features stand out rather prominently: 1. repeated negative Wassermann and allied serologic reactions in patient and parents; 2. bilateral ocular and auditory symptoms; 3. occurrence in young adults; 4. chronicity, with multiple unpredictable recurrences; 5. synchronous onset of ocular and of aural symptoms; 6. mildness of ocular symptoms; 7. aggravation of symptoms by changes in the weather; 8. striking variation in symptoms; 9. characteristic yellowish-white corneal opacities, tending toward vascularization; 10. evidence of iritis (cells in the anterior chamber and keratic precipitates); 11. leukocytosis and suggestive eosinophilia; 12. bilateral nerve deafness; and 13. constant condition of the cornea.   Ralph W. Danielson.

Silva, A. I. da. Familial dystrophy of the cornea. Rev. brasil. oftal. 7:113-129, March, 1949.

Four members of the same family were affected, two brothers and two sisters from 16 to 30 years of age. Five other children were not involved. The affection had first appeared at the ages of 7 and 5 years in the men, and in the women at 6 months. The periphery of the cornea was spared in every case. All four had extremely low vision. A small corneal biopsy in one showed epithelium in process of keratinization, irregular in thickness and generally atrophic. Bowman's

membrane was absent and replaced by amorphous hyaline structure. There had been inflammatory exacerbations. The author regards the cases as representing an atypical form of macular degeneration of the cornea. (9 figures, including 6 photomicrographs.).   W. H. Crisp.

Stansbury, F. C. Lattice type of hereditary corneal degeneration. Arch. Ophth. 40:189-217, Aug., 1948.

The lattice type of corneal dystrophy is a chronic, slowly progressive, familial disease of the cornea, inherited dominantly. It begins in the first decade of life, and usually in the first few months. It is characterized in youth by frequent recurrent erosions of the corneal epithelium, associated with severe photophobia, lacrimation and mild conjunctivitis. In adult life the recurrent attacks become less frequent and milder, but there is progressive loss of vision. The lesion is always bilateral. A detailed clinical and histologic description of the lesion is given. The etiology is unknown. The literature and classification of corneal dystrophies are reviewed. Five cases of lattice type degeneration are reported in detail. Keratoplasty was performed on one eye in each of three patients with favorable results in two. There is no assurance that the degeneration will not invade the transplanted tissue in time.

UVEA, SYMPATHETIC DISEASE, AQUEOUS

Braley, A. E. The etiology and treatment of uveitis. J. Iowa St. M. Soc. 39: 57-60, Feb., 1949.

The diagnosis and treatment of uveitis are uncertain and discouraging. Observations on supposed tuberculous uveitis are contradictory. Tubercle bacilli have been found in normal retinal tissue, and the adjacent choroid and ciliary body showed extensive inflammation but no bacilli. Tissues inoculated into guinea pigs produced no reaction. In other organs tubercle bacilli are almost always associated with the lesion. Other causes are also discussed. Rather extensive experimental studies of bacterial allergy and attempts to isolate a filterable virus are being reported. In the author's laboratory intracerebral inoculations of anterior chamber fluid from about 20 eyes with uveitis were made into mice and into fluid tissue cultures but revealed no infectious agent. Ground tissue from the iris and ciliary body of five eyes enucleated because of uveitis was incubated and inoculated intracerebrally into mice, guinea pigs, and rabbits. No organism was found. Typhoid vaccine is still the treatment of choice. Antibiotics and antihistaminics have been ineffective. Bacterial allergy is probably the most important cause.

F. M. Crage.

Casanovas, Francisco. Sarcoma of the ciliary body. Arch. Soc. oftal hispano-am. 9:184-188, Feb., 1949.

The interesting features were an iridodialysis produced by the tumor, which is typical of tumors of the ciliary body and is exceptional in choroidal tumors, the formation of pseudocysts in the ciliary procesess, and inflammatory phenomena. The latter are important in differentiating tumor and tuberculoma of the ciliary body. (2 figures.) Ray K. Daily.

Marín Amat, M., and Marín Enciso, M. Leucosarcoma of the iris treated by extirpation. Arch. Soc. oftal. hispano-am. 9:180-183, Feb., 1949.

A 46-year-old woman had a small symptomless growth in the iris of the left eye for 12 years. Then hemorrhages appeared which were slight and transitory for a few months and finally filled the eyeball and obscured vision. The growth, a leucosarcoma, was extirpated. (2 figures.)

GLAUCOMA AND OCULAR TENSION

Arruga, H. An adrenalin preparation similar to Glaukosan. Arch. Soc. oftal. hispano-am. 8:1206, Dec., 1948.

Arruga calls attention to a preparation under the name of Sol-inhal.

Ray K. Daily.

Barkan, O. **Technic of goniotomy for congenital glaucoma.** Arch. Ophth. 41:65-82, Jan., 1949.

Goniotomy is an operation for stripping or peeling embryonic tissue from the wall of the angle. If the cornea is clear, the operation is performed under direct vision with the aid of a prismatic contact glass specially devised for this purpose. If cloudiness of the cornea prevents the use of the glass, the operation is performed without it.

Goniotomy, which at the time of this writing had been performed on 76 eyes with infantile glaucoma, preserved useful vision in most cases. In 66 eyes pressure was normalized and vision maintained or restored over periods ranging from one to ten years. In 10 eyes the operation was unsuccessful. When combined with early diagnosis, it provided excellent visual results. The mode of action of goniotomy is discussed. The advantages, disadvantages, indications, contraindications and technic of goniotomy are described. The importance of early diagnosis and prompt operation is stressed.

Ralph W. Danielson.

Campos, R. **A combined antiglaucomatous operation, cyclodialysis with basal iridectomy.** Boll. d'ocul. 27:689-696, Nov., 1948.

To combat chronic simple and chronic "inflammatory" glaucoma, Campos modified Wheeler's suggestion to combine cyclodialysis and iridectomy by using a basal iridectomy instead of the complete iris excision which is too mutilating for common use. The peripheral iridectomy should be located at the site of the cyclodialysis. The latter is performed in the 12-o'clock region. A conjunctival flap is dissected to expose the upper rectus muscle and a bridle suture is introduced. Five mm. behind the limbus, a 2 to 3-mm. incision is made in the sclera, parallel to the limbus. A "first step" of cyclodialysis follows, separating the ciliary body only 3 mm. from the scleral incision without reaching the pectinate ligament. After that, another incision is made 1.5 mm. behind the limbus with a keratome, and a peripheral iridectomy is performed. The "second step" of the cyclodialysis follows. An Elschnig spatula is introduced into the anterior chamber through the first incision, and moved from the temporal edge of the coloboma to the 12-o'clock position, then from the nasal edge of the coloboma to the same meridional position. The spatula is withdrawn, re-introduced and the maneuver is repeated on the nasal side. (9 figures.) K. W. Ascher.

Crisp, W. H. **Early development of the filtration operations for glaucoma.** Ophth. ibero am. 10:211-221 (English); 222-230 (Portuguese), 1948. See Am. J. Ophth., 31:3, p. 277, 1948. W. H. Crisp.

Dellaporta, A. **Results of antiglaucomatous iridencleisis, and the value of early operation.** Acta ophth. 26:413-428, 1948.

This is a detailed analysis of the results of 224 cases operated by iridencleisis. It is just as effective as Elliott's operation without harboring the threat of late infection, and it is more effective than cyclodialysis. In noninflammatory glaucoma early operation was outstandingly more effective in preserving the visual field and reducing the tension. In late operations the number of failures was twice as large. These results are in conformity with those published by others. The earlier the operation is performed the better is the chance for normalization of tension and preservation of the visual fields. Of the 224 eyes, only 6 percent had free fistulization. The lining of the wound with protective uveal tissue accounts for the rarity of late infection after iridencleisis. (6 tables.) Ray K. Daily.

Díaz-Domínguez, D. **Glaucoma and excavation of the papilla.** Arch. Soc. oftal. hispano-am. 8:1219-1242, Dec., 1948.

This is an exhaustive review of the literature and a report of several cases of glaucoma without hypertension, in which careful investigation revealed transitory phases of hypertension. The size and depth of the excavation of the papilla have no relation to the degree of ocular hypertension. The absence of excavation in prolonged hypertension is accounted for by a diminished rigidity of the ocular walls; on the other hand, disproportional increase in the depth of the excavation is related to an increased rigidity of the ocular walls, and a vascular sclerosis in the circle of Heller. In many reported cases of glaucoma without hypertension transitory or intermittent hypertension were probably overlooked. Glaucoma is a disease of age, and the adjective "senile" may be applied to it legitimately. (5 visual fields.)   Ray K. Daily.

Esente, I. **Treatment of glaucoma with intravenously injected procaine.** Ophthalmologica 117:147-160, March, 1949.

Two to three hours after the intravenous injection of 10 to 20 cc. of a 1 to 2-percent aqueous solution of procaine the ocular tension of glaucomatous eyes drops. Acute glaucomas respond better than chronic ones. The injections must be given slowly but may be repeated two to three times daily. The possible mode of action of this medication is discussed.

Peter C. Kronfeld.

Friedenwald, J., Kronfeld, P., Dunnington, J. H., Chandler, P. A., and Vail, D. **Symposium: Primary Glaucoma.** Tr. Am. Acad. Ophth. pp. 169-237, Jan.-Feb., 1949.

Glaucoma may be primary, secondary, and congenital, and primary glaucoma may be chronic simple, acute congestive, chronic congestive, and absolute. Practically all congestive cases are of the narrow chamber angle type. Vasomotor disturbances alone are not considered causative until the chamber angle has become at least partially obstructed. Primary normal and wide chamber glaucoma is usually of the chronic noncongestive or simple type. In some cases sclerosis of the afferent arterioles of Schlemm's canal was observed. Primary wide angle glaucomas may include the low tension group. Sudden lowering of intraocular pressure apparently results in the inadequate filling of Schlemm's canal with blood. Hypotony from penetrating surgery may cause ciliary edema and change a wide into a narrow angle glaucoma.

Kronfeld, P. **Diagnosis.** Pp. 175-185.

The classification of glaucoma as to chamber angle simplifies the early diagnosis of primary types. The early diagnosis of the narrow angle groups is usually not difficult. Most congestive cases belong in this group. The biomicroscope, gonioscope and dark room test are valuable. The early stages of wide angle glaucomas are usually more difficult to recognize, and a routine procedure is outlined which will reduce diagnostic failure to a minimum. Perimetric findings and low tension glaucomas are briefly discussed.

Dunnington, J. H. **The surgical treatment of primary glaucoma.** pp. 213-224.

Surgical intervention should be promptly considered in narrow angle glaucomas, unless adequately controlled by miotics and hygienic treatment. Operations should, if possible, be performed between acute episodes. In narrow angle glaucomas scleroiridectomy is usually contraindicated after 48 hours; then iridencleisis is usually the operation of choice. The trephine and other forms of sclerectomy are more traumatizing and therefore of more limited value. Paracentesis is of no permanent value. In chronic glaucomas the age of the patient,

tension, visual acuity and fields, combined with structural ocular findings, determine the choice of iris inclusion or sclerectomy operation. In chronic narrow angle glaucomas obliteration of the angle and peripheral synechia are bad prognostic signs. Sclerectomy types of operation are usually less satisfactory than iridencleisis if extensive peripheral synechiae exist. In chronic wide angle glaucomas cyclodialysis and iridencleisis are usually preferable in less advanced cases and trephine or other forms of sclerectomy in the more advanced. Goniotomy is of greatest value in infantile glaucoma.

Chandler, P. A. **Complications of surgery.** pp. 224-231.

The causes of operative failures as well as the methods of prevention and their correction are briefly discussed. Failure in trephine operations may result from scar tissue closure in congested eyes, high tensions with subsequent lens dislocations and friable conjunctiva. Meticulous attention to details of the procedure are essential. Simple iridencleisis may not be sufficient in far advanced glaucomas, especially if the iris is atrophic.

Cyclodialysis should not be employed if the anterior chamber is very shallow, the tension high or if extensive peripheral anterior synechiae are present. Cyclodialysis should include one-third to one-fourth of the circumference.

Vail, D. **Review, summary and conclusions.** pp. 232-237.

The importance of classification of primary glaucoma by the type of angle is briefly discussed and illustrated. Repeated attacks of acute narrow angle glaucoma lay the foundation for synechiae which increase with each attack. Operations on narrow angle glaucomas tend to produce analogues of acute attacks. Trabecular pigment may be of no importance. Low tension glaucoma must be differentiated from pseudoglaucoma with cavernous atrophy. Gonioscopic examination of potential

glaucoma is advised. The early diagnosis of wide angle glaucomas may be exceedingly difficult and the five steps mentioned by Dr. Kronfeld are recommended. The importance of a synergistic combination of miotics of the different types is stressed. The authors of this symposium are in accord concerning the basic concept of the formation and drainage of the aqueous; the importance of recognizing narrow and wide angle glaucoma; the use of medical treatment especially for wide angle types only as long as it is demonstrably effective; and a careful choice of operation and thorough development of the operative techniques.

Chas. A. Bahn.

Lehrfeld, L. **Medical versus surgical treatment of glaucoma.** Arch. Ophth. 40: 332-340, Sept., 1948.

This paper is a plea for conservatism. There are innumerable cases of acute glaucoma in which operation has been performed and the tension reduced, but the visual acuity has been reduced also. The author does not have record of a single case of acute glaucoma in which a surgical procedure has not resulted in some loss of vision.

Ralph W. Danielson.

Leopold, I. H., and McDonald, P. R. **Di-isopropyl fluorophosphate (DFP) in treatment of glaucoma.** Arch. Ophth. 40: 176-188, Aug., 1948.

Di-isopropyl fluorophosphate has a prolonged miotic effect that results from an irreversible inactivation of cholinesterase. Its action is inhibited by the previous use of physostigmine or neostigmine. DFP successfully lowered ocular tension in 208 of 380 glaucomatous eyes. It was effective in concentrations ranging from 0.01 to 0.1-percent. Preparations of the drug in peanut oil were more effective than similar concentrations in liquid petrolatum. DFP lowered ocular tension successfully

in eyes with chronic glaucoma, acute glaucoma, buphthalmos, aphakic glaucoma, and glaucoma secondary to uveitis and exfoliating lens capsule, although other miotics had previously failed. The best results were seen in eyes with aphakic glaucoma. Decidedly fewer instillations of DFP were required to maintain a satisfactory ocular tension in eyes in which the tension was also controlled by other miotics. Disadvantages in its use include painful ciliary spasm, local sensitivity, and acquired resistance to its action. In six eyes a rise in tension followed its instillation. Retinal detachments have been reported to follow its use in patients with high myopia.   John C. Long.

Marín Amat, M. The true role of fistulating operations in the treatment of glaucoma. Arch. Soc. oftal. hispano-am. 8: 1249-1254, Dec., 1948.

The normal optic and metabolic functions of the eye are maintained by a neuro-vegetative intraocular center of regulation, represented by Muller's cells in the choroid, iris and ciliary body. All disturbances in the intraocular circulation, vascular or lymphatic, are compensated through this center, even if they originate extraocularly in the cortex, thalamus, medulla or hypothalamus. The primary cause of ocular hyptertension is an increase in the fluid content of the eye. Because of the compressibility of the venæ vorticosæ and Schlemm's canal, the hypertension impedes and may abolish the elimination of intraocular fluids. The interference with drainage is secondary to an overproduction of fluid. Antiglaucomatous operations should aim to decrease this fluid content of the eye by an attack on the regulating cells, situated at the root of the iris and in the ciliary body; they should in effect be arteriectomies or sympathectomies and diminish ciliary activity. Most effective are broad iridectomies and cyclodiathermies. External

operations on the sympathetic ganglia are ineffective. Fistulating operations are effective only to the extent in which they act on the primary factor of overproduction of fluid, through the concurrent iridectomy. Cyclodialysis acts by destruction of the ciliary body and not by providing drainage through the suprachoroidal space. Diathermy-coagulation of the ciliary body acts directly on the nerve cells that regulate intraocular circulation. Marín Amat is emphatic in the opinion that fistulating operations are indicated only in cases in which surgical interventions aiming at the removal of the primary cause, such as iridectomies and cyclodiathermies are inadequate.

Ray K. Daily.

Moreu, Angel. The role of the trigeminus in the regulation of ocular tension. Arch. Soc. oftal. hispano-am. 8:1193-1206, Dec., 1948.

Experimental data on dogs are presented to support the conclusion that excitation of the first branch of the trigeminal gives rise to an intraocular discharge of histamin, which through vasodilatation, increases the blood content of the uveal sponge, and raises the ocular tension. No modifications in tension were produced by the stimulation of the corneal plexus, but they appeared rapidly after irritation of the iris and ciliary body. The irritation was produced by a fine sharp needle introduced into the anterior chamber angle under gonioscopic observation, which punctured the iris or ciliary body; irritation of the iris was followed by a hyperemia of the ciliary vessels, a rise in tension, miosis, hyperemia of the iris and ciliary body demonstrable gonioscopically, and an increase of cells in the aqueous. Hyperemia of the ciliary vessels followed irritation of the cornea and conjunctiva. These experiments were repeated after modifying the neurovegetative ocular tone with mimetic and lytic

drugs. Parasympathomimetic drugs increased the effect of trigeminal stimulation and parasympatholytics were without effect. Sympathomimetics abolished the reaction of the trigeminal, and resection of the sympathetic and sympatholytic drugs exaggerated it. Acute rises in tension similar to acute glaucoma could be produced by blocking the vorticose veins concurrently with stimulation of the trigeminal. The experimental data are applied to the explanation of the pathogenesis of secondary hypertension in acute iridocyclitis. The rise in tension caused by an irritation of the trigeminus is not compensated because of the vasomotor paralysis, slowing of the circulation, and the obstruction in the venous and aqueous drainage incident to the disease. (6 graphs.)

Ray K. Daily.

Pallarés, J. Surprisingly favorable results of cyclodialysis in advanced cases of chronic glaucoma. Arch. Soc. oftal. hispano-am. 8:1244-1248, Dec., 1948.

The author's enthusiasm for cyclodialysis is based on three cases in which it was followed by a marked reduction in tension and an improvement in very narrow visual fields. (3 visual fields, 1 graph.)

Posner, A., and Schlossman, A. Syndrome of unilateral recurrent attacks of glaucoma with cyclitic symptoms. Arch. Ophth. 39:517-535, April, 1948.

Nine cases, forming a homogeneous group which represents a type of glaucoma intermediate between primary and secondary glaucoma, are described. The disease is unilateral. In three there was some heterochromia, and in each instance the lighter-colored eye was involved. Symptoms may be absent or there may be slight discomfort, colored halos or blurring of vision. Ocular hypertension may appear a day or so before, or simultaneously with, cells in the aqueous.

Within the next 24 hours postcorneal deposits are seen. Episodes may occur with varying frequency and without any apparent cause. It is proposed to call this condition a syndrome of glaucomatocyclitic crises. A tentative hypothesis is advanced which relates this syndrome to a disturbance of the autonomic nervous system. A classification of glaucoma associated with iridocyclitis is presented.

Rubino, A. and Pereyra, L. The eye and the diencephalon. V. The "luminous sensibility" in simple chronic glaucoma. Riv. oto-neuro-oftal. 23:227-236, July-Aug., 1948.

There is a constant reduction of luminous sensibility in primary glaucoma which does not seem related to the changes of vision, visual field or tension but is attributed to a lesion of the diencephalic centers and the thalamus. (6 figures, references.) Melchiore Lombardo.

Rubino, A. and Esente, I. The eye and the diencephalon, VI. Glycemic curve and "photo-glycemic reflex" in glaucomatous patients. Riv. oto-neuro-oftal. 23:237-243, July-Aug., 1948.

Ten patients with simple chronic glaucoma showed glycemic curves that suggested changes of the diencephalic centers and also an abnormal "photo-glycemic" reflex. These observations on carbohydrate metabolism support the new concept of the relation between the diencephalon and glaucoma.

Melchiore Lombardo.

Stocker, F. W., Holt, L. B., and Clower, J. W. Clinical experiments with new ways of influencing intraocular tension. Arch. Ophth. 40:46-55, July, 1948.

The influence of the "rice diet" introduced by Kempner for the treatment of hypertensive vascular disease on the ocu-

lar tension of nonglaucomatous patients was studied. All patients showed a striking and persistent reduction of ocular tension which did not seem to be directly dependent on the reduction of the blood pressure. It is believed that a relative depletion of chlorine and sodium ions in the tissues, including those of the eye, might be the underlying factor.

Ralph W. Danielson.

Vidal, F., Brodsky, M., and Travi, O. C. **The physiopathology of simple chronic glaucoma.** Ophth. ibero-am. 10:107, 1948 (Spanish) 122, 1948 (English).

The nature and influence of three stages are discussed in detail. The exact interpretation of each developmental type permits us to avoid in future the gloomy prognosis.   W. H. Crisp.

Weekers, R., and Humblet, M. **Angioscotoma and neuroscotoma of chronic glaucoma.** Acta ophth. 26:455-467, 1948.

Every patient with early glaucoma was examined exhaustively on the perimeter and on the Bjerrum screen to demonstrate the earliest field changes in chronic glaucoma. Goldman had pointed out that increase in size of the angioscotoma is produced not by an increase in the size of the retinal vessels but by a functional inadequacy in the retinal nerve elements due to a vascular disturbance. The earliest symptom of glaucoma is a change in the physiologic angioscotoma, which goes through the three stages: increase in size, fusion, and increase in density. At the poles of the blind spot where the angioscotomas are close to one another they coalesce as they increase in size. The phenomenon is often interpreted as enlargement of the blind spot. These early changes are reversible. An increase in the density of the angioscotoma is a sign of a graver circulatory disturbance and indicates an irreversible lesion of the nerve elements. An angioscotoma with increas-

ing density soon becomes a neuroscotoma. A neuroscotoma is easy to outline, and the examination should determine its position, extent, density, margins, and progress. They are arcuate in form, and extend nasally when they reach the nasal raphe. The peripheral extension of the arcuate scotoma accounts for the peripheral constriction of the nasal field. Extension in the temporal field constricts it until only a small centrocecal island of vision is left. The early visual loss of glaucoma is demonstrable only through patient and systematic perimetric and campimetric studies, with small test objects, and variable illumination. The diagnosis of these changes is important in that they form the indications for surgical intervention at a time when it can still be effective. (8 figures.)   Ray K. Daily.

CRYSTALLINE LENS

Gaines, S. R. **The role of retrobulbar neuritis in the management of senile cataracts.** New Orleans M. and S. J. 101: 390-391, Feb., 1949.

Many old people have markedly reduced vision although they have no lens changes. The visual loss is due to retrobulbar neuritis on an arteriosclerotic basis. The cavernous atrophy of the nerve head in "soft glaucoma" may be caused by pressure of the sclerosed internal carotid artery on the optic nerve. One may have arteriosclerotic optic atrophy without cupping of the disc caused by total or partial obliteration of small vessels. The atrophy may be diffuse or patchy, causing generalized depression of the visual field, sector defects, or central scotoma. Patients with lens opacities not dense enough to explain the loss of vision deserve careful visual field studies and the patient should be warned that the cataract operation will restore only central vision.

R. Grunfeld.

Gjessing, Harald. **A slight improvement of the common capsule forceps.** Acta ophth. 26:445, 1948.

By filing away the next to the last tooth of the capsule forceps used for removing the anterior capsule in cases of extracapsular extraction a small hole is formed through which the lens capsule herniates as it is being grasped by the teeth. Gjessing removes a sufficiently large portion of the anterior capsule with this forceps to prevent the subsequent development of secondary cataract.

Ray K. Daily.

Huerkamp, B. **Basically different types of lens opacities within the group called "cataracta syndermatotica".** Klin. Monatsbl. f. Augenh., 113:318-328, 1948.

The cataract of neurodermatitis starts behind the anterior lens capsule, involves the anterior cortex and very slowly and progressively the posterior cortex. Cataract in sclerodermy starts in the posterior cortex and the anterior parts of the lens remain clear. Lens opacities in poikilodermy at the same time in the anterior and posterior cortex as very fine grayish points. Both eyes are involved and maturity of the cataract is reached after days or months whereas the other forms of cataract may take years to reach maturity. The article contains a chart tabulating the most important differential points. (4 figures.) Max Hirschfelder.

Jaeger, A. **Surgery of luxated lenses.** Klin. Monatsbl. f. Augenh. 113:312-314, 1948.

The author reports the result of lens extraction in 10 eyes with subluxated and totally luxated lenses. Immanent glaucoma was the indication in some. The use of a capsule forceps is recommended whenever possible. Loop extraction was necessary in nine. Two of the three eyes with subluxation had a postoperative vision near 20/100; one had an intraocular hemorrhage. Those with total luxation were much less satisfactory and must be considered poor risks.

Max Hirschfelder.

Mejer, F. **Infection of the lens after perforating injuries.** Klin. Monatsbl. f. Augenh. 113:366-369, 1948.

Thirteen cases of extraction of infected lenses after perforating injuries are described. Conservative treatment is rarely successful in spite of the newer drugs and fever shock treatment. Whenever the infection is limited to the lens and the anterior part of the globe, a satisfactory result is possible. Four of the author's cases recovered sight after extraction of the infected lens. Max Hirschfelder.

Schott, J., and Dann, S. **Werner's syndrome: a report of two cases.** New England J. Med. 240:641-644, April 21, 1949.

Two cases of Werner's syndrome are reported. It is an abiotrophic process that first becomes manifest by slow growth during adolescence and graying of the hair at the age of twenty years. Its most striking manifestation is a change in the appearance of the skin which suggests scleroderma but is the result of atrophy of the subcutaneous fat and the underlying muscle. Star-like opacities develop chiefly at the posterior pole and the periphery of the lens. F. H. Haessler.

Thomas, C. I. **Cataract extraction by the suction method.** Arch. Ophth. 39:805-815, June, 1948.

The author describes a suction apparatus modified after the instrument of Dimitry. The suction method of cataract extraction is used to its greatest advantage when 1. the lens is hypermature, 2. the capsule is tense, 3. the capsule has exfoliated, 4. the lens must be dislocated

before it is tumbled or slid out of the fossa, and 5. the capsule is friable and will not stand any tension. Pitfalls of the operation are discussed and contraindications to its use are pointed out. An analysis of 618 cases of intracapsular extraction is presented to show the comparative frequencies of rupture of the capsule.

John C. Long.

Velhagen, K., Jr. Surgery of congenital and juvenile cataract. Klin. Monatsbl. f. Augenh. 113:305-312, 1948.

Failure in the operative treatment of juvenile cataract is usually due to poor surgery. The author discusses the various complications. He emphasizes the importance of corneal incisions without bleeding. Loss of vitreous is more dangerous in children than in adults. Traction on the zonula is often followed by phthisis. The author recommends simple discission for lamellar cataract in very young children and emphasizes the necessity of doing as small an operation as sule, shrunken cataracts and tough secpossible. Cataracts with thickened capondary membranes should never be pulled out. The procedure results in phthisis bulbi. A so-called double discission is recommended, introducing two small knives from each side through small limbal incisions at the same time and cutting from the pupillary center towards the pupillary periphery. A cut with scissors may sometimes be necessary, but is more dangerous. The posterior lens capsule should not be opened as long as cortical remnants remain in front of the secondary cataract. Linear extraction in one single operation is indicated in older children and young adults only. The author prefers to operate on children with dense lens opacities at the age of 12 months. He discusses the question of early surgery in such cases. (References.)

RETINA AND VITREOUS

Bedell, A. J. Diagnosis of retinoblastoma. Arch. Ophth. 40:311-316, Sept., 1948.

To illustrate the difficulty of diagnosis, six case reports are given, two of retinoblastoma and one each of angiomatosis retinae, leukosarcoma of the choroid, Coats's disease, and retrolental fibroplasia. Bedell advises against future pregnancy in a family in which more than one child has the disease. One case is not sufficient to condemn the family to a childless existence.   Ralph W. Danielson.

Bottasso, G. A case of retinal embolism of probable venous origin. Rassegna ital. d'ottal. 17:384-388, Nov.-Dec., 1948.

A 32-year-old man noted sudden loss of sight in the right eye 11 days after surgery for internal hemorrhoids. There was edema of the macula and in the area between it and the disc, and a sudden marked reduction in caliber at one point in an arteriole in the region. Treatment was ineffectual. It is assumed that a small embolus originated in a hemorrhoidal vein and produced a pulmonary infact from which a minute fragment found its way into one of the arteries to the eye.

Eugene M. Blake.

Carreras Matas, B. Difficulties in the diagnosis of retinal detachment. Arch. Soc. oftal. hispano-am. 8:873-878, Sept., 1948.

A woman, 40 yearrs old, had a central scotoma in the right eye, myopia, negative ophthalmoscopic findings and a recent puerpurium with a dead fetus. The diagnosis of retrobulbar neuritis was made, and treatment prescribed accordingly. Five weeks later the scotoma involved the upper nasal field, and funduscopy revealed a retinal detachment. In

the course of a perforating diathermy-coagulation a small hole was found close to the optic disc. Forty days after the operation the retina was completely re-attached, the visual field was normal, and the central scotoma corresponded to the coagulated area. The reasons for missing the diagnosis at the outset are discussed, and it is suggested that an examination of the visual field for blue, and biomicroscopy of the posterior pole of the eye might have helped to avoid the error. In retinal detachment, which disturbs the nutrition of the neuroepithelial layer, the field for blue suffers more than the red-green field. The greater magnification and intensity of illumination in biomicroscopy with a slitlamp might have revealed the retinal detachment. In general, however, this method of examination is more suitable for the study of details in a previously discovered disease than for the search for a lesion. (4 figures.)

De Berardinis, E., and Bonavolontà, G. **Tissue therapy in ophthalmology.** Boll. d'ocul. 27:753-772, Dec., 1948.

Among 35 patients with tapetoretinal degeneration and treated with intramuscular cod-liver oil injections 26 showed an improvement of variable degree during seven months. The authors feel that further prolonged observations will be needed. K. W. Ascher.

Di Luca, Giuseppe. **Retinal arterial occlusions.** Riv. oto-neuro-oftal. 23:106-130, March-April, 1948.

Studies of 12 patients from 16 to 76 years of age with unilateral or bilateral occlusion of the central artery of the retina or of its branches by angiospasm or endoarteritis are reported. (References and 10 figures.) Melchiore Lombardo.

Di Luca, G. **Clinical and statistical considerations of periphlebitis retinalis and recurrent vitreous hemorrhages of the juvenile eye and its connections with Buerger's disease.** Boll. d'ocul. 27:773-788, Dec., 1948.

Di Luca exhaustively studied 11 patients between 18 and 43 years of age with periphlebitis retinae or recurrent vitreous hemorrhages, and all but one showed evidence of tuberculous infection. Twenty patients with Buerger's disease were evaluated as to their ophthalmoscopic findings. Ten of the 20 showed sclerosis of the retinal arteries, 9 had engorged retinal veins, 8 peripapillary edema, 1 an inactive choroiditis, and 4 endarteritis of the retinal arteries. Summarizing his findings and those of other authors he found that among 184 patients with *periphlebitis and recurrent vitreous* hemorrhages, more than 71 per cent, had tuberculosis, and less than 1 percent showed signs of Buerger's disease. Among 138 patients with Buerger's disease only one had periphlebitis retinae and one recurrent vitreous hemorrhages. The patients with periphlebitis and recurrent hemorrhages belong to a markedly younger age group than those with Buerger's disease. There is no direct relation between th two fundus conditions and Buerger's disease. (References.)

News items should reach the editor by the 12th of the month*

MISCELLANEOUS

RESEARCH PROGRAM

Papers presented at the 18th scientific meeting of the Association for Research in Ophthalmology, Inc., Philadelphia, were: "Experimental studies on sympathetic ophthalmia," Dr. Raymond C. Collins, New York; "Correlation of microscopic and slit-lamp examination of developing hereditary cataracts in mice," George K. Smelser, Ph.D., and Dr. Ludwig von Sallmann, New York; "Curare and akinesia for ocular surgery," Dr. John R. Roche, New York.

"Experiments on fatigue of accommodation with asthenopic patients. II," Dr. Conrad Berens, New York, and Saul B. Sells, Ph.D., Randolph Field, Texas; "Some effects of injection of hyaluronidase into the anterior chamber," Dr. Jay G. Linn, Jr., and Lieut. Col. Thomas L. Ozment, Pittsburgh.

"Effects of metabolic poisons and of some other agents on intercellular cohesion in corneal epithelium," Dr. Wilhelm Buschke, New York; "A study of visual mechanism as revealed by the electrical activity of optic-nerve fibers," Dr. H. K. Hartline, Baltimore; "Nutritional supply of corneal regions in experimental animals," Dr. Albert M. Potts and Dr. Lorand V. Johnson, Cleveland.

"Studies on the physiology of the eye using tracer substances: Part III. Further studies on the steady-state ratio of sodium between the plasma and aqueous humor in the guinea pig," Dr. Roy O. Scholz, Baltimore; "Studies of the eye with radioiodine autographs," Dr. Ludwig von Sallmann and Beatrice Dillon, M.A., New York; "The cyanide sensitivity and cytochrome-C content of the crystalline lens," Dr. L. O. Ely and W. A. Robbie, Ph.D., Iowa City, Iowa.

"A study of the possible conversion of dehydroascorbic acid to ascorbic acid in the aqueous humor," V. Everett Kinsey, Ph.D., Boston; "The histochemical localization of cholinesterase," George B. Koelle, Ph.D., and Dr. Jonas S. Friedenwald, Baltimore; "Polysaccharides in ocular tissue," Dr. Robert Day, Baltimore; "Problems in the histochemistry of the eye," Dr. Jonas S. Friedenwald, Baltimore.

"Beta-ray application to the eye with description of an applicator utilizing SR⁹⁰," Dr. H. L. Friedell, Dr. C. I. Thomas, and J. S. Krohmer, M.S., Cleveland; "Beta irradiation: An evaluation of a radium-D applicator for ophthalmic use," Dr.

Fred M. Wilson, Chicago; "The effect of low voltage roentgen rays on the normal and vascularized rabbit's cornea," Dr. Harold G. Scheie, Dr. Richard H. Dennis, Dr. Richard C. Ripple, and Dr. Larry L. Calkins, Philadelphia.

SECTION ON OPHTHALMOLOGY MEETING

At the meeting of the Section of Ophthalmology, American Medical Association, Atlantic City, June 8th to 10th, the following program was given:

Chairman's address by Dr. M. Hayward Post, Jr., Saint Louis, and a symposium on ocular injuries conducted by Col. William Stone, Washington; Dr. W. Morton Grant, Boston; Dr. David G. Cogan, Boston; Dr. Brittain F. Payne, New York; Dr. Don Marshall, Kalamazoo, Michigan; Dr. Alston Callahan, Birmingham; and Dr. Derrick Vail, Chicago.

"A clinical study of 200 cases of retrolental fibroplasia," Dr. Merrill J. King, Boston, with Dr. William C. Owens, Baltimore, opening the discussion; "Retrolental fibroplasia: A study of its pathology," Dr. Parker Heath, Boston, with the discussion opened by Dr. Algernon B. Reese, New York; "Prophylaxis of gonorrheal ophthalmia of the newborn," Dr. James H. Allen and Dr. Luciano Barrere, Iowa City, Iowa, with Dr. Alan C. Woods, Baltimore, opening the discussion.

"The frequency of the occurrence of cataract in atopic dermatitis," Dr. Alfred Cowan and Dr. Joseph V. Klauder, Philadelphia, with Dr. William P. Beetham, Boston, opening the discussion.

"New trends in ciliary-body surgery for the relief of glaucoma," Dr. Gambiattista Bietti, Pavia, Italy, with the discussion opened by Dr. Derrick Vail, Chicago; "Flicker fusion field: III. Findings in early glaucoma," Dr. Paul W. Miles, Saint Louis, with Dr. Lawrence T. Post, Saint Louis, opening the discussion.

"General anesthesia for cataract surgery," Dr. H. Douglas Sanders and Dr. Norman L. Cutler, Wilmington, Delaware, with Dr. John H. Tucci, Boston, opening the discussion; "The age norms of refraction and vision," Dr. Felician J. Slataper, Houston, Texas, with the discussion opened by Dr. Alfred Cowan, Philadelphia.

"The syndrome of aneurysm of the intracranial carotid: Frontal headache with oculomotor nerve paralysis," Dr. Rudolph J. Jaeger, Philadelphia, with Dr. Frank B. Walsh, Baltimore, opening the discussion; "The use of curare in intraocular surgery," Dr. Daniel B. Kirby, New York, with Dr. Frederick C. Cordes, San Francisco, opening the discussion.

SECTION EXHIBITS

Among the ophthalmic exhibits shown in the Scientific Exhibition at the A.M.A. convention were: "Hydrodynamics of the aqueous veins," Dr. K. W. Ascher, W. M. Spurgeon, and Jean Schuff, Cincinnati; "The corneal lens: Theory and application," Dr. M. W. Nugent and Dr. Kevin M. Tuohy, Los Angeles; "Pathology of the eye: New technique for preparations," Dr. Brittain F. Payne, Dr. Joseph H. Krug, and Dr. Edgar Burchell, New York; "Pathology of the eye in old age," Dr. A. L. Kornzweig, New York; "Office bacteriology of the eye," Dr. Frederick H. Theodore, New York; "Kodachrome studies of the ocular fundus," Dr. Dan M. Gordon, New York; "Cerebral angiography related to ophthalmology," Dr. Donald J. Lyle and Dr. Frank H. Mayfield, Cincinnati; "Glaucomatous excavations," Dr. Peter C. Kronfeld, Dr. Roy O. Riser, and Dr. John T. Parker, Chicago.

Dr. Georgiana D. Theobald, Oak Park, Illinois, Dr. Edwin B. Dunphy, Boston, and Dr. Phillips Thygeson, San Jose, California, comprise the exhibit committee of the Section on Ophthalmology.

SOCIETIES

READING PROGRAM

Dr. S. Gordon Castigliano, Philadelphia, spoke on "The oral cavity; the physician and the dentist," and Dr. Benjamin F. Souders, Reading, spoke on "Ocular manifestations of tropical diseases and their treatment," at the 93rd regular meeting of the Reading Eye, Ear, Nose, and Throat Society, May 18th, held jointly with the Reading Dental Society.

MILWAUKEE SOCIETY HONORS DR. HAESSLER

The May 24th meeting of the Milwaukee Oto-Ophthalmic Society was a testimonial dinner for Dr. F. Herbert Haessler in honor of his appointment as clinical professor of ophthalmology, Marquette Medical School.

Dr. Haessler, abstract editor of the JOURNAL, gave up his private practice last January in order to devote all of his time to the teaching of ophthalmology.

Among the speakers for this occasion were: Dr. Gustave Guist, professor of ophthalmology, University of Vienna, who was special guest speaker; and Dr. John Hirschboeck, dean, University of Marquette Medical School, who spoke on "Plans and objectives in ophthalmological teaching at the Marquette Medical School."

Preceding the induction of Dr. Haessler to honorary membership in the society, the annual meeting and election of officers took place.

PERSONALS

GIVES MONTGOMERY LECTURE

Dr. Daniel B. Kirby, New York, gave the Montgomery Lecture at Trinity College, Dublin, on May 12th. The subject of his address was "The preparation of the whole patient for cataract surgery." On May 23rd, Dr. Kirby presented a paper on cataract surgery before the French Ophthalmological Society in Paris.

TO LECTURE IN MEXICO

On August 15th to 27th, Dr. Brittain Ford Payne, clinical professor of ophthalmology, New York University Medical College, surgeon and director of pathology, New York Eye and Ear Infirmary, New York, will give a series of lectures and demonstrations on the "Histopathology of the eye," in Mexico City.

Among the subjects to be discussed by Dr. Payne are: "Surgical anatomy and histology of the human eyeball," "Microscopic anatomy in detail," "Normal crystalline lens," "Diseases of the cornea, sclera, and anterior segment," "Granulomas of the eye," "Glaucoma and cataract," "Traumatic lesions of the eye," and "Intraocular neoplasms."

ANNOUNCEMENT

HOME STUDY COURSES

Home Study Courses in the basic sciences related to ophthalmology and otolaryngology, offered as a part of the educational program of the American Academy of Ophthalmology and Otolaryngology, will begin on September 1st and continue for a period of 10 months. Registrations must be completed before August 15th. Detailed information and application forms may be obtained from Dr. William L. Benedict, executive secretary of the Academy, 100 First Avenue Building, Rochester, Minnesota.

AMERICAN JOURNAL OF OPHTHALMOLOGY

CONTENTS

Frontispiece illustrating article by Frederick C. Cordes and Michael J. Hogan

ring hot chocolate when some of the contents splashed in his face. The left upper lid became infected. The infection subsided rapidly with Antipeol treatment. Healing was excellent and with a minimal formation of scar tissue.

DISCUSSION

One of the criticisms of the product (Antipeol) is that the ointment is too thick and difficult to remove. The greatest complaint made by the patients was that they could not get the ointment out from between the lashes without considerable rubbing. Possibly this aggravated the blepharitis which might otherwise have shown better response. If the filtrate could be incorporated in an ointment which had the consistency of the average ophthalmic ointment, this might be obviated. In addition, a softer ointment might permit better diffusion of the filtrate, with better results. At this time, a thought occurs that a filtrate of pyocyaneous germs in a suitable base might become an important adjunct in the treatment of pyocyaneous

ulcers of the cornea so common in industrial injuries.

CONCLUSION

While it is true that a great many local infections of the lids are self-limited and get well with the simple use of hot compresses, the rapid and excellent results in the 116 unselected cases reported and in a number of cases treated since are definite proof of the beneficial effects of bacterial filtrates on the ordinary pyogenic infections.

The results were more gratifying because of the complete absence of local allergic reactions. An unusual and striking phenomenon was the rapid relief from pain.

Some suggestions on the improvement of the product are offered. Wider treatment with bacterial phages and filtrates is recommended to avoid unnecessary allergic reactions and complications from the use of penicillin and sulfa drugs, which can always be used if the phages and filtrates fail.

REGENERATION OF THE CORNEAL STROMAL CELLS*

II. REVIEW OF LITERATURE AND HISTOLOGIC STUDY

A. EDWARD MAUMENEE, M.D., AND WALTER KORNBLUETH,† M.D.

San Francisco, California

In the course of studies on the fate of corneal grafts[1, 2] a clear understanding of the mode of regeneration of the corneal stromal cells was found to be essential in order to determine whether the cells in the donor cornea were replaced or not. A technique[3] was devised whereby the corneal cells could be destroyed with minimal inflammatory reaction and minimal disturbance of the corneal lamellae. It is the purpose of this report to describe the histologic appearance of these lesions and to establish the source of the regenerated stromal cells.

REVIEW OF THE LITERATURE

Regeneration of the corneal stromal cells has been studied extensively in the past. The types of injury used to produce destruction of these cells have been penetrating and nonpenetrating incisions into the anterior and posterior surface of the cornea and chemical burns of the cornea. Cell replacement in some cases of parenchymatous keratitis has also been studied.

It has been concluded from these observations that the stromal cells are replaced from: (1) Undamaged corneal corpuscles; (2) wandering cells from outside of the cornea; (3) a transformation of epithelial cells or endothelial cells into stromal cells; and (4) a combination of these sources.

Most workers have based their conclusions on the morphologic appearance of the cells in the regenerating area. The methods used in studying the regeneration of the stromal cells and the conclusions drawn from these studies are so similar in many instances that a detailed review of each report will not be given.

Gueterbock, Gussenbauer, Reich, Neelson and Angelucci, and others[4a-d] made incisions of various types into the corneas of frogs, rabbits, and dogs and concluded from their studies that the destroyed stromal cells were replaced from undamaged corneal corpuscles in the region of the lesions. They noted that mitotic figures appeared in the cells adjacent to the injury and that the cells became more spindle in shape before migrating into the injured area. The possibility that these newly formed cells could have originated from cells outside of the cornea was thought to have been eliminated by the scarcity of wandering cells observed in the undamaged part of the cornea.

The same conclusions were reached by Eberth,[5] Senftleben,[6] Homen,[7] and Klemensiewicz,[8] following studies on lesions produced by chemical injuries of the cornea. Elschnig[9] and Fuchs[10] studied the regeneration of stromal cells in human eyes which had been injured by inflammatory processes and had been removed for various reasons. They were not as dogmatic in their opinions as to the origin of the newly formed stromal cells but they also thought that the majority of the cells originated from undamaged corneal corpuscles. Fuchs observed the scarcity of cells containing mitotic figures and suggested that the stromal cells in some cases divided by amitosis.

Ranvier[11] offered the unique theory that wounds in the cornea were repaired by protoplasmic outgrowths from the stromal cells and not by a multiplication of these cells. Kruse,[12] who worked in Grawitz's laboratory, thought that the newly formed stromal cells arose from the "slumbering cells" of Grawitz.[13] He studied many tissues of the body and concluded that specific cells existed in the various connective tissues which could not be seen in normal tissue

with hematoxylin and eosin stain. If, however, the tissue was injured these cells became activated to repair the lesion and could be seen with routine stain. Neither of these theories has been confirmed.

Retterer[14] studied incisions in guinea pigs' corneas and concluded that the new stromal cells originated from transformed epithelial cells and a multiplication of the stromal cells by mitotic division.

Salzer[15a-e] made extensive studies on incisions performed from the external surface in the cornea of rabbits, guinea pigs, frogs, trout, chickens, pigeons, and salamanders. In a series of articles, he gradually came to the conclusion that the epithelial cells, which migrate into a wound made from the external surface of the cornea, are converted into stromal cells. As proof of this he stated that he was able to follow the transition from a typical epithelial cell to a spindle cell of the stroma.

He also thought that the nuclei of the newly formed corneal corpuscles showed a remarkable similarity to the nuclei of the epithelial cells. The protoplasma of the newly formed spindle cells (keratoblasts) stained with hematoxylin like the protoplasma of the epithelial cells.

Salzer was unable to find stromal cells in the process of multiplication and offered this as evidence against the participation of stromal cells in repair.

Wolfrum and Boehmig[16a-b] disputed the epithelial origin of stromal cells. They concluded from a series of experiments in which incisions were made into the posterior surface of the cornea that the stromal cells were replaced by mitotic and amitotic division of the corneal corpuscles and in some instances by a transformation of the endothelial cells. They thought that the leukocytes played no part in the regeneration of the stromal cells.

Hanke[17] studied perforating and nonperforating wounds in guinea pigs' corneas. He thought that the newly formed corneal corpuscles were derived from the undamaged stromal cells and, in some instances, from the endothelial cells in the deeper layers of perforating wounds. In order to determine whether or not macrophages participated in the repair of corneal stromal cells he tagged these cells by injecting trypan blue into the animals, systemically. A few cells containing this dye were found in the area of active repair. Hanke thought that these cells were not derived from outside of the cornea for he could not find cells containing the dye in the normal cornea between the lesions and limbus.

Von Wyss,[18] Bonnefont and Lacoste,[19] and Janyk,[20] on the other hand, have suggested that destroyed corneal cells are replaced by leukocytes or macrophages which wander into the cornea after injury. They thought that the stromal cells did not aid in this reparative process.

Pullinger and Mann[21] have recently studied rabbits injected with pontamine sky blue in which the corneal cells had been destroyed by applying a small droplet of liquid mustard gas to the center of the cornea. They were unable to follow the complete transition of macrophages containing this dye to stromal cells because the dye tended to disappear just at the time when the cells changed their characteristics.

However, they concluded from their experiments that most probably the principal source of newly formed corneal corpuscles was the conversion of macrophages. They pointed out that, embryologically, the corneal corpuscles were derived from wandering mesodermal cells which phagocytize vital dyes. They also stated that, in only a few instances, were corneal corpuscles observed in the process of division and therefore it was unlikely that these cells participated very actively in the process of repair.

Scelkunow[22] reported that regenerated stromal cells were derived from corneal corpuscles and leukocytes.

It may be concluded from this review of

the literature that newly formed stromal cells are derived from several sources but that there is no uniformity of opinion as to the source of these regenerated cells. The proof offered in most instances as to the origin of these cells has been based on routine histologic examinations. In only a few instances have special techniques been used to establish the source of the cells. Because of this diversity of opinion and the lack of substantial proof of any one theory it was thought that the source of the regenerating stromal cells should be investigated further.

EXPERIMENTAL STUDIES

The corneal cells in rabbits and rats were destroyed by freezing the tissue to −78°C. for 3 to 5 seconds according to the technique previously described.[3] In rabbits' corneas, 2-mm. and 6-mm. lesions produced a slight edema of the cornea which could be seen grossly 2 to 3 hours after freezing. This edema increased up to 24 hours, persisted for a few days, and gradually absorbed leaving the corneas entirely normal in appearance on gross and slitlamp examinations 5 to 7 days after freezing.

The persistence of the edema was proportional to the duration and area of freezing. Central corneal lesions on the whole caused less reaction in the conjunctiva and iris than peripheral injuries. Vascularization of the cornea was never observed in central injuries and only rarely were a few small capillaries noted to invade the cornea for a few millimeters after peripheral lesions. Secondary infection occurred in only a few instances in which over half of the corneal cells were destroyed at one time and there was persistent edema of the cornea.

Rats' corneas reacted in a similar manner but they normally contain more polymorphonuclear cells and tend to develop more inflammatory reaction. The advantage of studying rats' corneas is that the epithelium can be removed and a central 2- to 3-mm. strip consisting of the whole thickness of the stroma can be stained and examined under a microscope without sectioning. This allows a greater number of stromal cells to be observed at one time.

HISTOLOGIC STUDY

This study is based on 158 eyes removed at 5 minutes, 15 minutes, 30 minutes, 1 hour, every hour up to 4 hours, at a 3-hour interval up to 24 hours, every day up to 13 days, every other day up to 20 days, and then every 4 days up to 48 days.

Five minutes after the application of a 6-mm. solid brass applicator (cooled to −78°C.) to the cornea of a rabbit for three seconds the epithelium in the area of injury is missing. This loss of epithelium may be due to the adherence of the epithelium to the applicator.

Within 15 minutes after injury the endothelial cells in the region of freezing become flatter than normal and a few of the cells are detached from Descemet's membrane. Fibrinous exudate appears in the anterior chamber. In 30 minutes, edema can be seen in the posterior layers of the stroma. Two hours after injury a marked loss of endothelium can be observed and a few polymorphonuclear cells appear in the anterior chamber.

At this time the first changes are seen in the stromal cells. The corneal corpuscles in the area which has been frozen become thinner than normal and take a more basophilic stain. The stromal cells just adjacent to the injury become swollen. The edema which was present only in the posterior layers of the cornea can now be seen throughout the full thickness of the tissue. The corneal lamellae are separated by edema but otherwise appear normal.

At 4 hours after injury definite fragmentation of the nuclei of the endothelial cells (fig. 1) can be observed and more of these cells have become detached from the endothelium. The "stringlike" appearance of the stromal cells is more obvious. The edema
Fig. 1 (Maumenee and Kornblueth). Central freezing of rabbit's cornea (6 mm./3 sec.) four hours after injury, showing nuclear fragmentation of endothelial cells and stringlike stromal cells. (Hematoxylin-eosin stain. ×500.)
Fig. 2 (Maumenee and Kornblueth). Central freezing of rabbit's cornea (6 mm./3 sec.) 10 hours after injury, showing nuclear fragmentation of stromal cells. (Hematoxylin-eosin stain. ×500.)

of the stroma increases and a few polymorphonuclear cells can be seen outside of the vessels in the conjunctiva..

By 6 hours the endothelium is completely lost in the region of the injury. Fragmentation of the nuclei can be observed in the stromal cells and many of these cells have disappeared from the lesion.

At 10 hours most of the stromal cells have disappeared and those that remain show fragmentation of the nuclei (fig. 2). A few polymorphonuclear cells can be seen under the epithelium in the region of injury for the first time. The polymorphonuclear cells have increased in number at the limbus but the reaction is still not great. At 12 hours the cornea in the area which was frozen is practically acellular (figs. 3 and 4). The corneal edema has increased so that the thickness is now about three times greater than normal.

Very little further change is noted in the cornea until about 20 to 24 hours after freezing when definite signs of repair appear. Possible slight migration of the epithelium and endothelium occurs before this time but now regeneration of these tissues becomes definite.

The cells in the basal layers of the epithelium become flattened and at times spindle-shaped. They migrate in a single layer across the denuded cornea and the reëpithelized areas soon develop a double layer of cells. Frequent mitosis is noted in the region of repair. The endothelial cells also show evidence of repair. These cells become enlarged and spindle-shaped. They migrate individually so that at times there is a considerable space between the most advanced and next cell (fig. 5).

Mitotic figures (fig. 6) are also observed in these cells, a finding which is exceedingly rare in the normal endothelium. The stromal cells adjacent to the lesion, which up to this time have shown only an increase in basophilic staining, slight enlargement, and an increase in their protoplasmic processes, now
Fig. 3 (Maumenee and Kornblueth). Central freezing of rabbit's cornea (6 mm./3 sec.) 12 hours after injury, showing margin of lesion. (Hematoxylin-eosin stain. ×125.)
Fig. 4 (Maumenee and Kornblueth). Same cornea as in Figure 3, showing slightly more central area of the lesion. Notice complete absence of cells and edema of stroma. (Hematoxylin-eosin stain. ×125.)

show definite evidence of migration. Some of these cells become round and are difficult to differentiate from wandering macrophages with hematoxylin and eosin stain.

Other cells become more spindle in shape with long protoplasmic processes. Mitotic figures can frequently be seen in the cells adjacent to the acellular area.

Fig. 5 (Maumenee and Kornblueth). Central freezing of rabbit's cornea (6 mm./5 sec.) one day after injury, showing migration of endothelial cells. (Hematoxylin-eosin stain. ×500.)
Fig. 6 (Maumenee and Kornblueth). Central freezing of rabbit's cornea (6 mm./3 sec.) 36 hours after injury, showing endothelial cell in mitosis. (Hematoxylin-eosin stain. ×500.)

Polymorphonuclear cells are conspicuously rare as they have been during the whole course of these lesions. Small monocytes however become rather prominent in the conjunctiva at the limbus and can be seen in the normal corneal stroma and near the edge of the lesion. Occasional large monocytes can also be found in the conjunctiva and normal cornea. It is difficult to differentiate these cells from the stromal cells near the edge of the injured tissue.

During the next 12 to 24 hours, the epithelium completely covers the damaged area of the cornea. The endothelial cells continue to migrate over the injured region and usually completely cover the lesion by four days. At first these cells are round or oval in shape protruding like many knots into the anterior chamber. Within a day or so, however, they resume their regular rectangular shape.

The cells in the stroma continue to invade the acellular area in a very irregular manner, some cells advancing far ahead of others. These cells vary in appearance. Some are long and spindle-shaped, with one or more nuclei; others look like small and large lymphocytes; and still others like wandering histocytes or macrophages.

Frequent mitotic figures (figs. 7 and 8) can be seen but there are not enough cells in mitosis to account for the reparative process. The occurrence of multinucleated cells would suggest that division in some instances takes place by amitosis.

By 5 to 7 days after injury, cells have invaded the full extent of the injured area. Their number and appearance however are not normal (fig. 9). The edema of the stroma rapidly subsides about this time,

Fig. 7 (Maumenee and Kornblueth). Central freezing of rabbit's cornea (6 mm./5 sec.) three days after injury, showing corneal stromal cell in mitosis (anaphase). (Hematoxylin-eosin stain. ×500.)

and by 7 to 8 days the cornea is usually normal in thickness.

The new stromal cells gradually resume their normal appearance and number and, by 10 to 12 days, the cornea appears entirely normal. At no time during this process is there any disruption or disturbance of the corneal lamellae. Vascularization of the cornea did not occur in any specimen.

The above description of destruction and repair of corneal cells was obtained from central injuries of the cornea. Lesions made in the periphery of the cornea show similar changes except for a slightly greater invasion of leukocytes and occasional invasion of the stroma for 1 to 2 mm. by small capillaries.

Fig. 9 (Maumenee and Kornblueth). Central freezing of rabbit's cornea (6 mm./5 sec.) seven days after injury, showing newly formed stromal cells. (Hematoxylin-eosin stain. ×125.)

Fig. 8 (Maumenee and Kornblueth). Central freezing of rabbit's cornea (6 mm./3 sec.) seven days after injury, showing mitosing (metaphase) and regenerating corneal stromal cells. (Hematoxylin-eosin stain. ×500.)

It is difficult to study the mode of death in the stromal cells in vertical sections of the rabbits' corneas because, frequently, the complete cell cannot be seen in a single section. Full thickness preparations of rabbits' corneas stain too deeply to allow them to be studied in toto.

Three-mm. strips of rats' corneas which had been frozen for 3 seconds and removed at various times after freezing were therefore prepared. The staining technique used was similar to that described by Buschke, Friedenwald, and Fleischmann.[23] In these preparations the full thickness of the cornea could be studied under the microscope.

It is found that, after freezing a 2-mm. area of the cornea for 3 seconds, definite fragmentation of the nuclei of the stromal cells can be seen 2 hours after injury (fig.

10). The first evidence of nuclear change is an agglutination of the chromatin into a single large clump or into many small clumps. The diffuse homogeneous staining of the nucleus becomes lighter and the clumps become more intensely basophilic. These clumps frequently migrate to the margin of the nucleus and the remainder of the nucleus becomes so pale that it can be seen only with difficulty.

Some of these cells then burst and liberate

perforating injuries. It was not possible to determine to what extent either of these two types of cells participated in the regeneration of the stromal cells nor was it possible to determine with certainty whether or not only one of these two types of cells was the sole source of the newly formed corneal corpuscles. In order to answer these latter questions further experiments were devised to study the source of the regenerated stromal cells.
Fig. 10 (Maumence and Kornblueth). Diagram of nuclear fragmentation of corneal stromal cells of rat's cornea after freezing of cornea (2 mm./3 sec.). (1) Nucleus of normal keratocyte. (2 to 6) Various stages of nuclear fragmentation.

their granules while others shrink so the nuclei look like bits of string with 3 to 4 knots tied in it. A similar change has been observed in the stromal cells following injury by mustard and nitrogen mustard gases.[24] By 10 to 12 hours after freezing, all of the stromal cells had disappeared from the rats' corneas in the area of injury.

Several interesting conclusions were obtained from these histologic examinations.

1. The stromal cells are destroyed by nuclear fragmentation following freezing.

2. Remarkably little inflammatory reaction accompanies extensive destruction of corneal cells after this type of injury.

3. All of the cells in the full thickness of a 6-mm. area of the cornea can be destroyed and stromal cells will regenerate without leaving any residual opacity of the cornea if the lamellae are not disturbed.

4. The corneal stromal cells appear to regenerate from the undamaged stromal cells and from wandering macrophages in non-

FURTHER EXPERIMENTAL STUDIES

Participation of macrophages in regeneration of keratoblasts. A macrophage has been defined by Maximow and Bloom[25] as a cell which is capable of taking up particulate matter and storing foreign substances brought to it in colloidal solution. The simplest criteria for deciding whether a cell of the connective tissue or blood is a macrophage is the elective storing of colloidal vital dyes. The concentration of the dye must be weak for even epithelial cells will become filled with dye granules in concentrated solutions.

It is not our purpose to enter the controversial discussion of either the nature or the origin of these cells. It will suffice to mention that the macrophages participate in the phagocytosis of foreign material and repair of damaged tissues in the body. They may originate from mitotic division of preexisting fixed or wandering macrophages, by hypertrophy and development of lymphocytes

and monocytes, and by direct assumption of phagocytic activity of cells having mesenchymal potencies of development.

Tissue-culture studies of monocytes, macrophages, and fibroblasts indicate that these cells are not fundamentally different from one another but merely various stages in development of the same basic type of cell. Carrel and Ebeling[26a, b] have shown that by varying the culture media and environmental conditions tissue cultures of monocytes, macrophages, and fibroblasts may be converted from one type of cell to another.

Ebert and Florey[27] have observed the transformation of monocytes into fibroblasts in vivo by punching holes in rabbits' ears and inserting glass chambers into these areas. These chambers then became filled with blood clots. The macrophages of the blood stream were tagged by systemic injections of vital dyes (Pontamine sky blue, trypan blue, and vital new red). By the use of microphotography and microscopic examination through the glass window they were able to observe the invasion and transformation of the tagged monocytes into fibroblasts in these blood clots.

The ability of macrophages or wandering tissue histiocytes to change into fibroblasts is now generally accepted. The corneal stromal cells do not differ markedly from fibroblasts elsewhere in the body for they are derived from the same embryonic source and have the same morphologic appearance. It is, therefore, probable that damaged corneal corpuscles are replaced in some instances by macrophages originating outside of the cornea. In order to test this hypothesis the following experiments were devised.

Rabbits weighing approximately 2 kg. were injected intravenously or subcutaneously with 45 cc. per kg. of a 1-percent trypan blue solution divided into three weekly injections of 10 cc. each.

Twenty-nine corneas were injured by freezing and the eyes were removed after 3 to 30 days, fixed in Zenkers solution, imbedded in paraffin, sectioned, and stained with lithium carmin. In all eyes, trypan-blue granules were found in extravascular macrophages in the conjunctiva and iris.

The damaged corneas could be divided into two groups depending on the number of cells containing trypan blue. In corneas with dry-ice injuries at the limbus and with complete injuries, from 50 percent to 75 percent of the cells contained dye granules

Fig 11. (Maumenee and Kornblueth). Freezing (3 sec.) of whole cornea of rabbit saturated with trypan blue, 21 days after injury. Showing trypan blue granules in corneal stromal cell. (Lithium carmin stain. ×750.)

in the regenerated area. In the corneas with central lesions only a very occasional cell was found containing the dye.

In the early stages of repair, the tagged cells were round and looked like wandering macrophages. After complete recovery had occurred, the dye-containing cells in the stroma looked like otherwise normal corneal corpuscles (fig. 11). These cells were scattered evenly through the previously damaged area.

In 15 control animals saturated with trypan blue in which the corneas were not frozen, the dye was never found in the corneal stromal cells. This experiment indicated that macrophages participated in the replacement of stromal cells in peripheral and extensive injuries of the cornea but they had little to do with the repair of central lesions.

The presence of trypan-blue granules in the stromal cells cannot be considered as absolute evidence that macrophages are transformed into stromal cells; for it was possible that macrophages containing trypan blue could have entered the cornea and, at a later time, either died or expelled their granules which were then phagocytized by the stromal cells.

Stokes[28] has shown that trypan blue injected into the anterior chamber is phagocytized by the stromal cells if the posterior surface of the cornea is injured. Therefore the above experiments are suggestive but they cannot be considered as complete proof that macrophages replace injured corneal corpuscles.

In another group of rabbits in which half of the cornea was injured, it was noted that the new stromal cells appeared as rapidly from the limbal side, where there were no corneal corpuscles, as they did from the corneal side. This occurred before cells were found in the central portion of the lesion so the new keratocytes could not have originated from corneal cells. It was also noted that central 6-mm. lesions of the cornea healed only 1 to 2 days more rapidly than did 3-mm. injuries around the entire periphery of the cornea. The area of the peripheral lesions is approximately 4 times that of the central one, so if only the stromal cells participated in the repair, and the cells did not divide at a greater rate due to more extensive injury, it should have taken considerably longer for the peripheral lesion to heal.

Finally, as more extensive lesions were found to heal without residual damage to the cornea, it was thought that absolute proof of participation of cells from outside of the cornea could be obtained if all of the stromal cells were killed. To this end whole corneas were frozen by repeated applications of the metal cylinders.

Frequently these corneas became vascularized and edema persisted in the dependent portions of the cornea for 2 to 3 weeks. Some of these corneas ulcerated in the lower portions and healed with rather dense scars. However, in many of the corneas the superior portion regained its normal clarity except for a light vascularization. The failure of these corneas to heal as well as the less extensive lesion was thought to be due to the extensive destruction of the endothelium or to the destruction of some essential substance in the normal stroma.

It had been noted previously in routine histologic studies of the central lesions that the endothelium recovered more rapidly than did the stromal cells. It was, therefore, thought that if one half of the cornea was frozen, and after an interval of two days the other half and one millimeter of the originally damaged cornea was frozen, it would be possible to destroy all of the stromal cells and at the same time leave undestroyed some of the more rapidly migrating endothelial cells.

The boundary of the upper and lower half of the cornea was established by making a superficial scar in the cornea with the point of a hypodermic needle, and the two halves of the cornea were frozen as described.

Histologic examinations of corneas injured in this manner revealed that either all of the stromal cells were killed or not more than 1 or 2 percent of the cells remained in the posterior central 2 mm. of the cornea.

Regeneration of the stromal cells occurred from the periphery and was similar to the repair of other less extensive peripheral lesions of the cornea except for slightly more inflammatory reaction. Approximately two weeks after injury, the corneas fre-

quently appeared normal clinically but, on histologic examination, the stromal cells were still not normal in number, distribution, and size (fig. 12).

In most instances the corneas regained a normal histologic appearance about three weeks after operation. In a few eyes the peripheries of the corneas for about 1 or 2 mm. were invaded by blood vessels. The response of the regenerated stromal cells was normal to a second injury by freezing and these corneas supported corneal grafts as well as did normal eyes.

It may be concluded from these experiments that cells other than normal stromal cells can participate in the regeneration of keratocytes. These cells probably are the monocytes of the blood stream or the fixed macrophages of the limbal tissues which have been activated by the injury.

Participation of stromal cells in regeneration of keratoblasts. Experiments devised to prove that the stromal cells are a source of regenerating corneal corpuscles have not been as conclusive as those demonstrating the participation of the macrophages. However, some observations have been made which strongly suggest that the corneal corpuscles contribute to the replacement of the destroyed cells.

In the experiments previously mentioned, in which the animals were saturated with trypan blue, only an occasional cell containing the dye was found in the regenerated damaged area if only the center of the cornea was frozen. This is in contrast to a relatively large number of dye-containing cells found in peripheral and whole injuries of the cornea.

Secondly, in lesions in the periphery of the cornea, where half of the cornea was frozen, migration of cells and mitotic figures were found on the stromal side of the lesion before an appreciable number of wandering cells had passed through the normal cornea to reach the edge of the lesion.

Indirect evidence that the corneal corpuscles might be a source of the regenerat-

ing cells is the fact that stromal cells can be cultivated in tissue culture. These cells have the same morphologic appearance as do the cells in the intact cornea (figs. 13 and 14). While these findings are not absolutely conclusive they suggest that the stromal
Fig. 12 (Maumenee and Kornblueth). Regeneration of corneal stromal cells nine days after freezing of whole cornea of rabbit, showing regenerated epithelium and endothelium. Slight edema of stroma, newly formed corneal stromal cells. (Hematoxylin-eosin stain. ×125.)

cells do aid in the reparative process of corneal lesions.

These experiments demonstrate that all of the cells in the full thickness of the cornea may be destroyed and, if the lamellae are not disrupted, the cornea will regain its normal clinical and histologic appearance after several weeks. The keratoblasts which replace the destroyed stromal cells originate from the remaining keratocytes and wandering macrophages from outside of the cornea.
Fig. 13 (Maumenee and Kornblueth). Tissue culture of normal stromal cells of rabbit's cornea. (Giemsa stain. ×125.)

It is clear then that, if one is to establish with certainty whether or not the stromal cells in a donor corneal graft are replaced, both the keratocytes in the grafted cornea and the macrophages of the recipient animal, or the stromal cells of the donor cornea, must be tagged.

The problem of tagging these cells is not an easy one for it must be remembered that any foreign substance introduced into the donor cells may be expelled and be phagocytized by the recipient cells if the donor cells are injured or destroyed.

Fig. 14 (Maumenee and Kornblueth). Tissue culture of normal stromal cells of rabbit's cornea, showing mitosis (metaphase). (Giemsa stain. ×500.)

SUMMARY

Previous investigators have suggested that the destroyed corneal stromal cells may be replaced by migration and multiplication of undamaged corneal corpuscles and by invasion of cells from outside of the stroma. Most of the evidence set forth by these workers has been based on routine histologic studies. In this report, the mode of repair of various-sized lesions has been described in which all of the cells in the full thickness of the cornea have been destroyed by freezing. This type of lesion causes very little inflammatory reaction and, when the injury has been completely repaired, the cornea appears normal on both clinical and histologic examination.

It has been shown that keratoblasts can be derived from two sources in nonperforating lesions of the cornea: (1) The macrophages or fixed-tissue histiocytes which have been stimulated to migrate by injury to the cornea, and (2) the activated normal corneal cells. Nonirritating lesions in the center of the cornea are repaired primarily by undamaged stromal cells. Similar lesions in the periphery of the cornea are repaired by wandering macrophages and undamaged stromal cells.

These findings indicate that, if it is to be proven whether or not the stromal cells are replaced in a donor corneal graft by tagging the cells of the recipient, it will be necessary to identify both the keratocytes and macrophages. Of course, it may be possible to solve this problem by tagging only the stromal cells of the donor cornea.

CONCLUSIONS

1. Rabbits' corneas will regain their normal clinical and histologic appearance after most, if not all, of the stromal cells have been destroyed by freezing.

2. The stromal cells die by nuclear fragmentation after freezing.

3. Destroyed corneal stromal cells are replaced by migration and multiplication of undamaged corneal corpuscles and by a transformation of wandering macrophages.

OPHTHALMIC MINIATURE

To George Whatley

Passy, May 23, 1785

. . . By Mr. Dollond's saying, that my double spectacles can only serve particular eyes, I doubt he has not been rightly informed of their construction. I imagine it will be found pretty generally true, that the same convexity of glass, through which a man sees clearest and best at the distance proper for reading, is not the best for greater distances. I therefore had formerly two pair of spectacles, which I shifted occasionally, as in travelling I sometimes read, and often wanted to regard the prospects. Finding this change troublesome, and not always sufficiently ready, I had the glasses cut, and half of each kind associated in the same circle. . . . By this means, as I wear my spectacles constantly, I have only to move my eyes up or down, as I want to see distinctly far or near, the proper glasses being always ready. This I find more particularly convenient since my being in France, the glasses that serve me best at table to see what I eat, not being the best to see the faces of those on the other side of the table who speak to me; and when one's ears are not well accustomed to the sounds of a language, a sight of the movements in the features of him that speaks helps to explain; so that I understand French better by the help of my spectacles. . . .

A FURTHER, VERY DELICATE TEST FOR ASTIGMATIC AXIS, USING THE CROSS CYLINDER WITH AN ASTIGMATIC DIAL AND WITHOUT USE OF LETTER CHARTS*

WILLIAM H. CRISP, M.D.
Denver, Colorado

AND

GEORGE H. STINE, M.D.
Colorado Springs, Colorado

The purpose of the procedure as to astigmatic axis proposed in the paper presented by Crisp[1] at the meeting of the American Ophthalmological Society in 1942 was to afford a delicate control test for axis in astigmatic errors, especially of low amount, in which the test for axis with cross cylinder and test letters seemed insufficiently definite and reliable. That test utilized the wagon-wheel type of astigmatic dial, more particularly the axis chart either of Lancaster and Regan or of Verhoeff.

In the course of the preliminary clinical and photographic studies in relation to that test for axis, it became obvious that several other astigmatic dials might yield interesting results along the same lines, and brief consideration was given to the use of a rotating single cross for the purpose.

Stine proceeded to devote further attention to these possibilities, and later reported to Crisp his studies and observations. From these Stine had evolved the new test, which Crisp now proposes shall be known as the "Stine test for astigmatic axis." Both of the present writers have continued to employ this new test during the past 2 or 3 years, and have found it more definite and freer from complications than any other test known to them.

The new test is of surprising delicacy and simplicity, although like other subjective tests it demands full understanding and cooperation on the part of the patient. Like Crisp's test it is generally used as a control after preliminary testing for axis with the cross cylinder and the letter chart, and in

the light of any evidence which may be furnished by ophthalmology, skiascopy, or an astigmatic dial. In the larger astigmatic errors it may not have to be resorted to at all, although even here it may sometimes clear up doubts. In the small astigmatic errors (to which some workers pay little or no attention, but which may be quite important) it is most valuable.

The rotating cross is most conveniently and expeditiously used with a pulley mechanism for remote control from the examiner's chair near the patient, although some refractionists will rely (less conveniently) upon the services of an office helper for changing the position of the lines of the cross. Ophthalmologists who refract with a mirror and laterally inverted charts will, of course, have their charts within arm's length. The only disadvantage of the test as compared with the combined use of cross cylinder and letter charts or wagon-wheel chart is that, for absolute accuracy, the position of the rotating cross should be changed with each change of axis of the cylinder in the trial frame, although a discrepancy of a few degrees in the placing of the cross lines is usually of little practical importance.

At each step of the procedure, the lines of the rotating cross are made to straddle exactly the axis of the correcting cylinder in the trial frame. That is to say, the two lines of the dial should stand at 45 degrees to either side of the axis of the trial cylinder. The cross cylinder, usually the 0.12D. or the 0.25D., is held so that its axes correspond with the two axes of the rotating cross (that is at 45 degrees with the axis of the trial cylinder), and the cross cylinder is turned

or "flipped" in the same manner as in testing for axis with the letter chart.

The patient is asked to say with which position of the cross cylinder the two lines of the rotating dial appear more nearly matched as to blackness or sharpness, or with which position of the cross cylinder there is the lesser, amount of contrast between the two lines. The cylinder in the trial

If the choice has been made, and the position of the lens in the trial frame is changed, the position of the rotating cross must also be changed so as to straddle exactly (or at least approximately) the new position of the axis of. the trial cylinder.

The final stage of the test is reached when the patient insists that the variation of emphasis, or the reversal of sharpness or
Fig. 1* (Crisp and Stine). Basic error of camera lens, rendered astigmatic, represents a final need for correction with +1.0D. cylinder axis 90°. For these two photographs the correcting +1.0D. cylinder had been placed inaccurately with its axis at 80 degrees. The two lines of the rotating cross were set respectively at 35 and 125 degrees. The cross cylinder was first placed with its plus axis at 35 degrees, and then with its plus axis at 125 degrees. The choice as to relative uniformity is obviously for the second of the two positions, indicating that the correcting plus cylinder should be turned toward 90 degrees. Astigmatic difference between the two lines in A is 0.59D., and in B, 0.09D.

frame is then moved toward the corresponding axis of the cross cylinder (plus toward plus, minus toward minus) in the position which gives greater uniformity of the lines or the lesser contrast between them.

* *Note as to illustrations.* For definiteness of illustration the basic error of the camera lens was that of mixed astigmatism, requiring a final correction with −0.25D. sph. ⊃ +1.0D. cyl. ax. 90°, and the 0.12D., cross cylinder (−0.12D. sph. ⊃ +0.25D. cyl.) was used. In actual practice it will be found that similar sharp differentiation by the patient is usually obtainable with such a weak cross cylinder and when dealing with a correcting cylinder as low as 0.25D.

The astigmatic differences between the two lines of the dial in the meridians shown in the illustrations were determined by the use of Percival's[3] equation for obliquely crossed cylinders and the law as to square of the cosine.

blackness from one line to the other, is equal in both positions of the cross cylinder; and, as under the test with cross cylinder and letters, the patient's accuracy may be cross-examined by turning the trial cylinder to each side of the selected position and repeating the test.

The patient may occasionally misunderstand the test and may answer paradoxically. Like other tests, this one is usually more reliable in the absence of active accommodation, although sometimes less accurate if the patient's vision is appreciably fogged. The use of a slightly over- or under-correcting trial cylinder affects the accuracy of the test practically not at all, although a slight overcorrection may often increase its sensitivity.

Very occasionally, determination must be made between conflicting results as to the use of this test and the use of letters with

It seems worth while to point out that, subject to spherical measurements, it is possible to accomplish all the measurements
Fig. 2 (Crisp and Stine). For this pair of photographs the correcting +1.0D. cylinder had been inaccurately placed with its axis at 100 degrees. the cross was set with its lines at 55 and 145 degrees respectively, and the cross cylinder was held with its plus axis first at 55 degrees and then at 145 degrees. The choice is obviously for the former position, indicating that the axis of the correcting plus cylinder should be turned toward 90 degrees. Astigmatic difference between the two lines is 0.09D. in C, and 0.59D., in D.
Fig. 3 (Crisp and Stine). For these two photographs the correcting plus cylinder was placed with its axis in the proper position, namely at 90 degrees. The rotating cross was placed with its lines respectively at 45 and 135 degrees, and the cross cylinder was held with its plus axis first at 45 and then at 135 degrees. There is obviously no choice as to the "equal inequality" of sharpness of the two lines on the rotating cross, indicating that the correcting cylinder is now at the proper axis. Astigmatic difference between the two lines is 0.25D. in both E and F.

the cross cylinder. But, generally speaking, the test with cross cylinder and rotating cross is as delicate and reliable as any procedure in refractive work, or more so.

(axis and strength) for astigmatism by means of the rotating cross, without resort to the letter chart. As demonstrated by Crisp in 1917,[2] the rotating cross may be

conveniently used in combination with a low cross cylinder for extreme refinement as to the exact fraction of astigmatism.

For this purpose, the axis having been determined, and the cross having been rotated so that one of its lines coincides with the axis of the trial cylinder, the cross cylinder (usually the 0.12D.) is held with the plus or minus axis alternately parallel with the axis of the trial cylinder. If both lines of the cross are actually equal, each position of the cross cylinder will slightly sharpen one of the lines of the cross and will slightly blur the other.

Thus, the patient's selection may be made to discriminate as to the error being slightly above or slightly below an exact eighth of a diopter of astigmatic difference. If the patient's response is paradoxical, all that is necessary is to inquire which position makes the two cross lines more equal in sharpness. The definiteness of this test may, of course, be vitiated by the presence of irregular astigmatism.

As to the axis test which is the main topic of this paper, a further application of the same principle may be made during determination of the axis by cylinder skiascopy. In this application, a cross cylinder of proper strength (as demonstrated by experience in the individual case) is held with its axes at 45 degrees with the axis of the cylinder before the patient's eye, and the examiner decides which way there is less suggestion of uncorrected astigmatism. But, as stated in regard to use of the test at the trial case (subjective test), in most patients, except those with larger errors or amblyopic eyes, such doubts may be settled more expeditiously and more conclusively along subjective lines.

FIXATION DISPARITY AND THE FUSIONAL PROCESSES IN BINOCULAR SINGLE VISION*

KENNETH N. OGLE,† PH.D., FRANCES MUSSEY, M.A., AND
AVERY DEH. PRANGEN,‡ M.D.
Rochester, Minnesota

INTRODUCTION

We have two eyes, therefore two retinal images, but we experience ordinarily a single perception of space. The normal physiologic and psychologic means through which this phenomenon takes place are called the fusional processes.

If, while one is looking at a distant object, a prism, base-out (for example), of not too high power is suddenly interposed before one eye, momentarily two objects are seen. These two, however, immediately move rapidly toward each other, the speed seeming to increase as the separation becomes less, as though each were attracted to the other by a magneticlike force. Then they suddenly coalesce, the final single impression giving no hint of its dual character. This phenomenon is said to illustrate the compulsion for fusion, a reflex to prevent diplopia. Under this compulsion eye movements occur such that the eye behind the prism turns to fixate the image of the object now seen through the prism. The movements of the eyes necessary for the reunification of the images are known as fusional movements. As usually stated, once the attention is directed to a given object the reflex to fusion so directs the pointing of the eyes that the images on the two retinas will fall on corresponding retinal elements or as near as possible to those elements. When this has taken place, one assumes that the neural excitations that arise from the two eyes are transmitted as "cortical" images to identical centers or regions of the visual cortex where unification takes place, the unification occurring prior to the conscious awareness of the perception.

The ophthalmologist needs a measure of the strength of the compulsion to fusion as an indication of the efficiency of the binocular visual mechanism and its ability to cope with muscle imbalances. The only measures available are the so-called prism vergences or fusional amplitudes. In the test for these, the eyes of the patient are directed to a target and then forced to converge (or diverge) by means of prisms placed before the eyes, base-out (or base-in). The prism power in each case is gradually increased until the patient reports a doubling of the target. At this report the prism power is noted. The findings so obtained for the convergence and the divergence are used as a measure of the fusional ability of the patient. Sometimes the prism strengths at which "blur" occurs and at which fusion is regained are also considered. Attempts are made to relate these data to the degree of lateral heterophoria present and finally to the ocular comfort of the patient.

That prism vergences are, at least in part, measures of the fusion ability is clear, since the fusion reflex cannot be separated from the convergence mechanisms and since it must demand particular muscular synergies of the oculorotary muscles of the eyes. However, it is questionable whether fusion power alone is being measured.

In prism vergence tests, probably three variables are involved: (1) The degree of the forced convergence (or divergence), (2) the strength of the fusion compulsion reflex, and (3) the degree to which the otherwise normal accommodative-convergence reflex is altered or embarrassed. The stimulus to accommodation (the target distance) is constant throughout the test.

The introduction of prism power before the eyes ordinarily sets up a stress in the normal accommodative-convergence reflex relationship, as long as the images remain fused. An accommodative change demanded by the changed convergence does not occur because of the compulsion to maintain clear vision, and it has been shown that over fairly wide limits the accommodative change in these tests is small, except as the prism strength approaches the diplopia point.[1]

In the prism vergence test it is the increasing stress in the convergence-accommodation reflex together with that of the musculo-mechanical processes which is pitted against the compulsion for fusion as prism power is increased. Diplopia occurs either when that stress is so great as to overcome the reflex innervation to maintain single binocular vision or when the mechanical limits of the oculorotary muscles are reached. Certainly, there is an expenditure of energy involved, and also a fatiguing of the muscles in the process. Both the magnitude of this stress and the strength of the fusion compulsion will undoubtedly vary from individual to individual.

Experimental evidence indicates that in spite of the compulsion to register the dioptric images of the two eyes as near as possible on corresponding retinal points, there occur an actual small deviation of the eyes and a corresponding slipping of the cortical images, although fusion is still maintained.

Identical target patterns observed on the two sides of the stereoscope will appear under normal conditions single, and then the images of these patterns are said to be "fused." Dissimilar (and unfusable) details *centered* on each of the same two patterns will under certain conditions appear decentered, that is, will appear displaced relative to each other, in spite of the fusion of the images of the identical patterns. This displacement occurs especially when the observer is heterophoric, or when the convergence and its normal corresponding stimulus for accommodation are altered. This phenomenon has been designated a *fixation disparity* (formerly, a "retinal slip") because the evidence indicates that the retinal images of the point of fixation may be actually disparate.

While this phenomenon may be a common observation among those who use the stereoscope or haploscope, it was Lau[2] who first described and correctly interpreted it while performing experiments on a different problem. He did not recognize any relationship between it and phoria.

He used targets, as illustrated in Figure 1A, in a haploscope, before the left and right eyes. Each target consisted of a long central line and a pair of shorter parallel lines that extended only to the center of each target. On one, the two short lines could be adjusted laterally by means of a screw, and the displacement could be measured by a scale and vernier. While the observer fixated the central line, and its images were fused, Lau adjusted the one pair of lines until the two opposing ones appeared in alignment. In every case, he found that both lines had to be displaced a small distance in the *same* direction. The magnitude of the displacement increased somewhat if the convergence of the arms of the haploscope was increased.

The interpretation given was that the true chief rays for the corresponding elements at the foveas of the two eyes were actually diverging slightly behind the position of the fused central line, the line of fixation.

Hofmann[3] reported the lag in the pointing of the eyes with rapid movements of the arms of the haploscope. Also, in commenting on Lau's work he expressed the belief that the phenomenon was associated with the interference in the normal accommodation-convergence reflex.

Lewin and Sakuma[4] set a playing card on each side of the haploscope; a four of diamonds before one eye and a five of diamonds before the other as illustrated in figure 1D. On looking into the haploscope the observer easily fused the images of the

four outer diamonds. The central diamond seen by only one eye, however, appeared decentered with respect to the outer four, especially as the convergence of the arms of the haploscope was changed.

In 1928, under the designation of "retinal slip," Ames and Gliddon[5] reported experiments with the haploscope in which targets (fig. 1B or fig. 1C) were used. They were able to show that the direction of the dis-

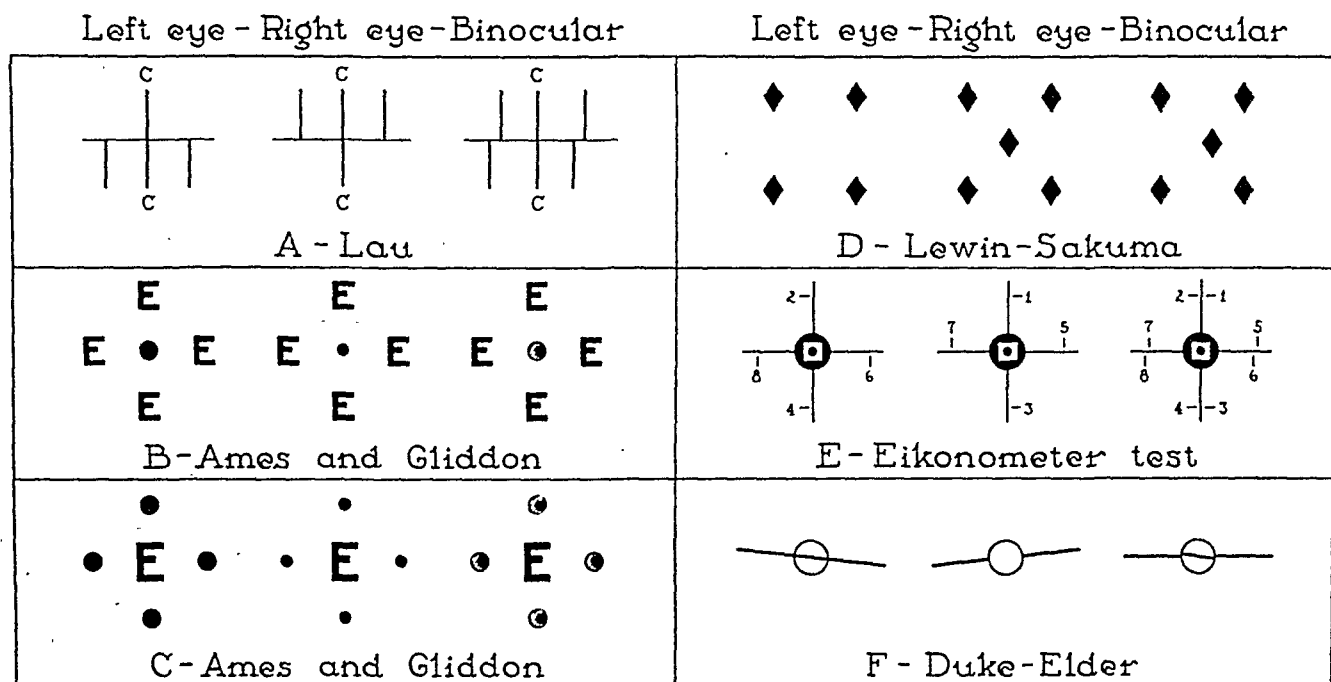
arrows seen by the left and right eyes on each side of the binocularly observed center appear displaced in the same direction. In fact, this displacement appeared to be a contributing factor to the lowered precision of measurements in the horizontal meridian, compared to those in the vertical, especially at the reading distance. The apparent magnitude of the displacement cannot be predicted, however, by the degree of the phoria.


Fig. 1 (Ogle, Mussey, and Prangen). Types of targets used by different authors for haploscopic observation with which fixation disparity was evident.

placement of the small discs within the larger ones was generally the same as the direction of the phoria of the observer. Also, they found a fair correlation between that convergence of the haploscope arms necessary to eliminate the displacement of the discs, and the magnitude of the phoria measured under the same conditions. The close similarity of the results from the two types of targets suggests that the phenomenon occurs irrespective of whether the fusion is in the central or in the more peripheral parts of the binocular visual field.

In the use of the eikonometer with the direct comparison targets (fig. 1E),[6, 7] it is a common observation that for the average patient who has heterophoria the opposing

Duke-Elder[8] illustrates a pair of targets (fig. 1F) which show that this same phenomenon can also occur as a cyclotorsional displacement of the monocular images compared to the binocularly fused portions of the targets.

This phenomenon rests on the well-known fact that disparate images in the two eyes can be fused, if that disparity is not too great, that is, if they fall within the so-called Panum fusional areas.[9] These areas increase with peripheral angle; they are 6 to 10 minutes of arc near the macula. Disparate images are those which do not fall on corresponding retinal elements of the two eyes. Images which fall on corresponding points of the two eyes give rise to the ex-

perience of the same *primary* subjective sense of direction, as though each eye were used alone.

Were it not for the existence of the fusional areas, physiologic diplopia (or, better, double images) could be demonstrated for all images of objects in space which did not fall exactly on corresponding retinal points. Thus, in the fusion of disparate images, where a single sense of direction is experienced, that subjective direction must be a compromise between the primary directions associated with the two noncorresponding retinal elements on which the two disparate images are falling.

Objects in the binocular visual field which are so arranged (for example, by haploscopic, Polaroid, or red-green glass methods) that they can be seen only by one eye are experienced in a subjective direction corresponding to the primary uniocular organization of the retinal elements on which the images fall, unless those images are near other images of binocularly seen contours the images of which are fused.[5]

Therefore, if the eyes tend to overconverge or overdiverge, owing to innervations or mechanical stresses ordinarily manifested as a phoria when the eyes are disassociated, they could actually deviate from exact fixation, so that the images of the point of fixation would be disparate to an extent limited by the size of Panum's fusional areas. The subjective direction of the fused images of the point of fixation would be a compromise between the two foveal elements in the two eyes on which the images fell as in normal stereoscopic vision. Objects in the field of view seen monocularly would be seen in the subjective direction according to the primary characteristic of the retinal elements on which the images fell.

That this is actually the case is illustrated by data that have been obtained for the longitudinal horopter[10] as determined by the nonius method. In Figure 2,* the eyes fixate

a point on an object at F. On either side a number of narrow vertical rods are so mounted that they can be moved nearer or farther along fixed tracks. Before the eyes is placed a special illuminated screen with apertures cut out in such a way that, except for the fixation object F, the upper halves of the rods are seen by one eye, and the lower halves are seen by the other eye. All the rods are properly shielded from the surroundings and are observed against a uniformly illuminated background. As any rod is moved along its track the two halves of the rod appear displaced laterally relative to each other, the apparent displacement changing with the position of the rod. The observer adjusts the position of each rod until the two halves appear collinear, that is, in the same subjective direction. The rod at this position, then, by definition, has images in the two eyes that stimulate corresponding retinal meridians. Experiment shows that generally the esophoric subject tends to set all the rods in a curve that lies entirely in front of the point of fixation (fig. 2a), while the exophoric subject tends to set all entirely behind the point of fixation (fig. 2b). Thus the images of the point of fixation are actually disparate, uncrossed in the first instance and crossed in the second.

The phenomenon of fixation disparity, which is found in a majority of subjects, implies that the cortical images arising from the two eyes are actually slipped or displaced a small amount with respect to each other. The angle of fixation disparity is a measure of the degree to which the images have slipped, in the same sense that Panum's area, although measured as a retinal dimension, pertains to a cortical area within which disparate images are fused. The processes involved in the compulsion for fusion normally strive to keep the images from the two eyes as nearly as possible on corresponding points. The phenomenon of fixation disparity shows, however, that the fusion is not exact when a tendency for a disassociation exists (a heterophoria), although the unification of the images is preserved.

---

* In these figures, for simplification in representation, the angle of fixation disparity is shown as though originating in only one eye.

Fixation disparity as a measure of the displacement of the cortical images will depend on the strength of the innervations and stresses of heterophoria, the strength of the fusion processes themselves, and the amount and complexity of the detail in the binocular field of view.

The purpose of this paper is to report a series of systematic measurements of the fixation disparity as influenced by a number of factors. The experiments were prompted

pair of Polaroid plates (5-cm. square) before the two eyes with the planes of polarization at right angles to each other. This Polaroid attachment could be turned down out of a field of view, and the two plates could be interchanged before the eyes if desired. The target for fusion stimuli consisted of Snellen letters projected by a lantern, the total field subtending an angular size of about 20 degrees. A small central area of a given size could be blanked out at
Fig. 2 (Ogle, Mussey, and Prangen). Schematic representation of horopter experiments which show that the point of fixation may not have images that fall on corresponding points.

by the thought that the fixation disparity might be an estimate, if not an actual measure, either of the strength of the fusional reflex or conversely of the strength of those forces—innervational, anatomic, and so forth—which tend toward an incorrect pointing of the eyes, while the images of the two eyes are actually fused.

PRESENT EXPERIMENTS

DISTANT-VISION TEST

Instrumentation. On an aluminum-coated screen, set up 2.5 meters from a subject's eyes, patterns and special test configurations were projected by suitable lanterns (fig. 3). The subject observed the screen through a phorometer, to which had been attached a

the center of the target and thus appear black to the subject. The size found convenient is a square that subtends a visual angle of about 1.5 degrees to the subject. With this center no stimuli for fusion are present within the foveal regions of the two eyes, but details for fusion exist everywhere outside this area.

The test configuration was projected on the blank square at the center of the screen by a second lantern into which a special slide arrangement had been built. The test details (see insert in fig. 3) consisted of a horizontal bright line, 28-cm. long and 5-mm. wide, and a pair of opposing (vernierlike) short vertical bright lines (arrows), 2.3-cm. high and 2-mm. wide (2.5 minutes of arc).

The arrows were polarized by Polaroid

film in the slide, so that one arrow would be seen by one eye and the other by the second eye, when viewed by the subject through the Polaroid plates. The upper arrow was fixed (stationary) but the lower could be displaced horizontally by means of a special mechanical arrangement in the lantern, which was operated by a screw and knob on the outside.

The displacement of the two arrows was

The general illumination of the room was kept subdued, and the luminosity of the screen and fusion detail were the same throughout the experiments. The binocular visual field was restricted wholly to the details on the screen.

Procedure. The phorometer is adjusted to the subject's head so that the eyes are centered. With the Polaroid plates before the eyes, the visual acuity of each eye is checked
Fig. 3 (Ogle, Mussey, and Prangen). Perspective drawing of the instrumentation used to measure fixation disparity.

read by the experimenter from an accurate *dial indicator on the lantern, to an estimated 0.2 minute of arc (angle subtended to the subject), which is well within the maximal sensitivity found. By means of a shutter arrangement, the lower arrow could be occluded or flashed onto the screen at the will of the operator.*

A light-green filter could also be placed over the upper arrow, if needed for making the identification of the arrows easier for the subject. The long horizontal line prevented fusion of the arrows and possibly reduced any tendency for a vertical deviation.

by means of the Project-O-Chart, the test target being projected on a screen. After this the phoria is estimated by the Maddox rod and also by the double prism test, a spot of light being projected on the screen in a room totally dark.

The target (with the 1.5-degree square) and the test arrows are then projected on the screen. With the Polaroid plates removed (both eyes observing the target), a determination of the dial reading is made for which the arrows appear in alignment, as well as of the least perceptible displacement (*a measure of the precision*) that can be detected. The operator instructs the subject

to look at the upper arrow, and then he flashes the lower arrow for a fraction of a second, after which he asks the subject whether that arrow was to the right of, to the left of, or was centered with the upper arrow. Between flashes the lower arrow is displaced to a new position. By the method of limits the average midpoint and precision are determined. The zero of the dial indicator is then adjusted to that reading for

position and the limits can be found within which he reports that the two arrows appear aligned. The actual displacement of the arrows is expressed by the angle, in minutes of arc, subtended at the eyes of the subject.

The experiment then proceeds by the determination of the fixation disparity for different values of prism power introduced by Risley rotary prisms* before the patient's eyes. For most subjects the prism power

* B.O. = base-out; B.I. = base-in

which the subject reports that the arrows are in alignment. This procedure eliminates the constant personal and instrumental errors. Only small variations between subjects are found.

The Polaroid plates are raised and the operator checks that the right eye sees only the upper arrow and the left sees only the lower arrow, and that ghost images are absent. By means of the shutter the lower line is then exposed for short intervals of about 0.25 second, and the subject is asked to judge whether this arrow was right or left of the upper arrow, or even with it. By adjusting the amount of displacement, and obtaining the patient's response, the average

was placed alternately base-out and base-in; the base-out in 4Δ steps and the base-in in 2Δ steps. The alternation of base-out and base-in procedure was found necessary to avoid cumulative effects.

Thus, while following to some degree the procedure in the test for fusional amplitudes, here one measures any deviation of the eyes

---

* It is unfortunate that rotary prisms introduce optical distortion. However, the advantages of the continuously adjustable prism power over the fixed steps of loose prisms, the axes of which are also difficult to adjust accurately, outweigh the possible disturbing effects of the distortion. Cursory experiments showed that this distortion had no significant effect on the measurements, in spite of the fact that theoretical arguments might anticipate such effects.

from their positions for exact fusion that may occur during the procedure. The change in the actual deviation during the test provides new data for studying the fusional processes as the eyes are subjected to changes in convergence by prisms and changes in the stimulus to accommodation by lenses.

parity and the limits within which the arrows appeared aligned are given. The direction (sign) of the deviation is taken as positive if it indicates an overconvergence of the eyes and as negative if the deviation
Fig. 4 (Ogle, Mussey, and Prangen). Relationship between the displacement of the polarized arrows, when they appear aligned, and the existence of an overconvergence or underconvergence of the eyes (fixation disparity).

Results. Typical data obtained are given in Table 1, and with others are illustrated in figures which follow. In the first column of the table, the prism power used is listed in the order in which the data were taken. In the two columns for each subject, the corresponding measure of the fixation dis-

indicates an underconvergence (overdivergence), that is, positive if the eyes are actually converged in front of the target or the geometric position of that target when prisms were used and negative if actually converged behind the target. Figure 4 illustrates schematically the positions of the arrows when they appear aligned, and the patient overconverges or underconverges relative to the target fixated. When prisms are used

before the eyes, of course, the images of the targets are so displaced that the eyes must converge or diverge if fusion is to be maintained.

The results of eight subjects are shown in Figures 5 and 6. In these graphs, the positive for convergence and negative for divergence. The measured fixation disparity in minutes of arc is plotted on the ordinate, being taken as positive if the deviation of the eyes is convergent and negative if divergent. It is evident that a large proportion
Fig. 5 (Ogle, Mussey, and Prangen). Typical data of subjects for whom the fixation disparity changes with forced convergence and divergence caused by the prisms before the eyes.

difference in the angle of convergence caused by the prisms compared to that for the 2.5-meter observation distance, measured in meter angles,* is plotted on the abscissa.

---

* The meter angles are readily obtained by dividing the total number of prism diopters by the interpupillary distance (in cm.), or roughly by 6. Meter angles are to be preferred over prism diopters or centrads, for they indicate more clearly the degree of convergence, and the corresponding demand on the accommodative mechanisms of the two eyes.

of all subjects exhibit a fixation disparity of different amounts, even when no prisms are used.

Inspection of Table 1 and Figures 5 and 6 shows that points representing the data for each subject describe a sigmoidlike curve, the shape of which is different for different subjects. However, two fairly definite types of curves are distinguishable. Typical graphs illustrating these two groups are shown in Figure 5 and in Figure 6.

Consider for discussion the data for W. A. P. in Figure 5. This subject is nearly emmetropic, with a visual acuity of 6/6 in both eyes, but shows an esophoria of 6 to 8 prism diopters for the 2.5-meter visual distance. With no prisms before the eyes (or the rotary prisms set for zero power), the two arrows had to be displaced 6.6 minutes

forced convergence would be manifested as an exophoria or a decreased esophoria if the fusion were not present, or as a change in the fixation disparity in the direction of a divergence. Such a reaction is demonstrated in this subject.

When prisms are placed base-in before the eyes a divergence of the eyes is forced, and
Fig. 6 (Ogle, Mussey, and Prangen). Typical data of subjects for whom the fixation disparity changes only slightly with forced convergence except at the limits of the fusional amplitudes.

of arc for them to appear aligned. This finding shows that the eyes were actually over-converged by 6.6 minutes of arc, which is in the same direction as the phoria.

When prisms are placed base-out before the two eyes, a convergence is necessary if fusion is to be maintained. This convergence of the eyes is made, but if the convergence-accommodation reflex is active, this convergence will be resisted because the accommodation cannot change appreciably without blurring the vision. This resistance to the

the reverse behavior in the fixation disparity is to be expected. Since the limits of prism vergences base-in at this fixation distance* are not large, the fixation disparity increases rapidly because the point of diplopia is quickly reached.

---

* For the fixation distance b, the distance from the target to the true fixation point Δb is given sufficiently accurately by $\Delta b = b^2/2a \tan \delta$, where δ is the fixation disparity and $2a$ is the interpupillary distance. For a visual distance b = 2.5 meters, this distance is roughly 3 cm. for a fixation disparity of 1 minute of arc.

Considerable difference between subjects is found in the limiting prism power for forced convergence caused by prisms base-out. On approaching that point, fusion may become too unsteady for reliable measurements and diplopia may occur intermittently. In several subjects (fig. 5), the data could not be obtained to the point of diplopia because of blurring, micropsia, and the ocular discomfort associated with the sustained convergence.

Precision of the data. One of the striking aspects of these data is the smallness of the quantities being measured and the precision within which they are obtainable. As is the case in many other psychophysical measurements, the observer feels that his judgments are very uncertain, but the actual objective accuracy proves surprisingly great.

If the visual acuity is high and the muscle balance is fairly normal, it is usual to find the limits within which the two arrows appear in alignment of the order of 1 minute of arc, and often less. The precision decreases with lowered visual acuity, and decreases considerably as the degree of the forced convergence or divergence becomes large, because the relative positions of images seem more unstable and liable to change (see table 1).

Several subjects, however, showed poor precision for the entire curve, in spite of good visual acuity and low phoria. It should be clear that the limits as determined here are larger than the mean error or the standard deviation would be in other types of experimental technique.

Repeatability. Data of the nature of those described in these experiments cannot fail to vary somewhat from day to day, depending on rather intangible factors associated with the individual. For some subjects the precision of measurements seemed to vary from one day to the next for no obvious reason, although fatigue, previous excessive use of the eyes, and even disinterest may have been specific factors. However, in spite of this variation, the general curve obtained

for a given subject after the lapse of several days agreed remarkably well with that previously obtained.

Figures 5 (L. D.) and 6 (A. G.) show two sets of such data identifiable by the circles and triangles. A small training effect is to be expected, but this seems to manifest itself in an increased precision and an increased amplitude of base-out prism vergence, rather than a change in the curve that represents the data. This must not be taken to imply that no changes are found, for frequently the second curve may be displaced from that taken first by a small degree, in the same sense that the phoria will change from day to day.

The particular technique used in exposing the arrow also generally had no significant effect on the curve obtained. In one technique the lower arrow was not flashed at all, the subject merely reported when he saw it to the right and when to the left of the upper arrow, as it was slowly displaced one way and then the other by the operator. The flashing technique was preferred, for it tended to reduce any alignment of the two arrows due to "desire for symmetry" and any influence of after-images, although these factors actually appeared to have only a minor effect, if any.

The small normal involuntary eye movements that are always present and which appear to increase with the stress accounted for occasional spurious responses. As the prism vergence approached the point of diplopia, fusion of the images became more uncertain, and here greater discrepancies in the repeated data were found. However, the values for the fixation disparity were already comparatively large in these regions, so that the curves themselves were only slightly modified by the variations in data. Reversing the Polaroid plates before the eyes, so that the arrows would be seen by opposite eyes, had no influence on the data.

For some subjects a second set of data obtained immediately after the first resulted in a slightly different curve. An accumulative

effect of the sustained use of prisms base-out toward the end of the test appeared to leave a residual esophoric stress evident by the vertical displacement of the curve and sometimes also by an increase in the slope (rate of change of the deviation with convergence) especially in the center of the curve. The effect may persist for several hours after the original experiment.

Care was taken not to obtain data for a curve immediately after prism vergence tests or unusual use of the eyes. In order to avoid cumulative effects during the experiment, the prisms, base-out and base-in, were alternated and frequent short rest periods were allowed. This influence of sustained base-out prisms on fixation disparity is interesting, for in obtaining prism vergence limits it is believed that the use of prisms base-out has less effect on data subsequently obtained than has the use of prisms base-in.[11]

Subject groups. An inspection of the curves selected shows rather strikingly the manner in which the subjects tend to fall into two groups according to the characteristics of the curves found. Subjects with curves intermediate between these two will probably be found, however. In the first group (fig. 5) the fixation disparity increases with the forced convergence (or divergence) of the eyes, and in the middle range the increase is almost directly proportional to the prism power. For these subjects, as the prism power is increased, the cortical images from the two eyes increasingly "slip" and the fusion of these images becomes increasingly less exact, until finally a confusion and then a diplopia occurs. Although the rate of change in the deviation with prism power suggests itself as a measure of the strength of the fusion reflex (the higher, the poorer the fusion), this is not borne out.

In the second group (fig. 6) the eyes maintain more or less the same degree of fusion, over wide ranges of forced convergence, as evidenced by the fact that the fixation disparity changes little between the limits near which sudden increases are found. The fusion of the two images for these subjects appears to be tightly held in spite of the increased prism power. Even for high degrees of forced convergence certain of the subjects showed only a small increase in the disparity (data K. N. O. and J. W. H.), until the point was reached where abrupt changes might be expected.

This second type of curve is not unexpected, for it might be anticipated that the fusional processes would hold the images tightly together during the entire prism vergence test, until a sudden giving way would occur at the limits with resultant diplopia. However, one would expect the fixation disparity to be zero between these limits. The anomalous factor shown in these data is that more or less constant actual fixation disparity is maintained between those limits. The precaution taken at the beginning of the measurements to determine the "zero" for each observer precludes the possibility that this displacement is a constant personal or instrumental error. The direction of this disparity in the level portion of the curve appears generally to be in the direction of the phoria.

Blurring the retinal images. There would be reason for expecting that the fusion in the face of opposing stresses would be more difficult when the retinal images are blurred, because all contours on which fusion will depend would be less distinct. However, it is well known that in prism convergence tests on the major amblyoscope or synoptophore the fusion of the images seems to hold well even after the images are so blurred as to be almost unrecognizable. The fixation disparity curve as obtained here also does not change appreciably when the images of both eyes are blurred by plus ophthalmic spherical lenses at distant vision or with occluder (special etchedlike) glasses.*

---

* These glasses were supplied by Dr. E. D. Tillyer of the Scientific Department of the American Optical Company. They consist of a series of glasses manufactured by a special process for reducing visual acuity in fixed steps.

However, if the image of only one eye is blurred, the fixation disparity does change with prism vergence, which indicates a less exact fusion. In these experiments the images were blurred by a +1.0D. sph. and the special occluder glass, both of which reduced the acuity of the eye to about 20/70. The effect of the blurring of the image of one eye on fixation disparity was somewhat different according to the two groups of subjects described previously. Figures 7 and 8 show the results obtained. In Figure 7, the curve changes markedly when the image is blurred, both for forced convergence and for forced divergence. In Figure 8, the change appears as a vertical displacement of the curve and occurs more significantly for divergence than for convergence.

Peripheral fusion. If the details for fusion are limited more and more to the peripheral

Fig. 7 (Ogle, Mussey, and Prangen). Influence of blurring the image of one eye on the fusion.

visual field, the fixation disparity curves change markedly, although again this is different in the two groups of subjects. By increasing the size of the blanked-out square in the projected fusion pattern on the

screen, in the center of which the vernier arrows are seen, the images which can be fused are restricted more to the periphery of the retinas.

Voluntary eye movements do not occur,

Fig. 8 (Ogle, Mussey, and Prangen). Influence of blurring the image of one eye on the fusion.

for the eyes are fixated at the center if they are to see any displacement of the arrows. Squares used to test this effect were of angular sizes of 0.75, 1.5, 3, and 6 degrees of arc subtended at the subject. The results obtained on two subjects, as examples of the two groups, are illustrated graphically.

In the first case (fig. 9) for a given convergence the fixation disparity increases rapidly as the size of the blanked-out area increases. Since Panum's areas in the periphery are many times larger than those in central vision, such increased disparity is possible while still maintaining fusion. The precision of the data decreased also. The response of this subject is entirely consistent with the previous data (compare Figure 5 for F. M.).

Figure 10 shows how peripheral fusion influences the fixation disparity in the second type of subject (compare Figure 6 for K. N. O.).

The data were obtained for the series of target sizes at each prism setting, in the same order as shown in Table 1; hence the

Fig. 9 (Ogle, Mussey, and Prangen). Influence of peripheral fusion on fixation disparity.

results found were not cumulative effects of the forced vergences. Again the data are consistent. The fixation disparity increases as the fusion is pushed into the periphery, but here this is evident by a vertical displacement of the curve in the convergent direc-

Fig. 10 (Ogle, Mussey, and Prangen). Influence of peripheral fusion on fixation disparity.

tion. As the forced convergence increases, the deviation then changes rather slowly toward the divergent direction.

For the subject whose data are illustrated in Figure 9, the curves for different-sized, central targets deviate even more if a red glass is used before one eye and a green glass before the other (fig. 11). This suggests that a red-green visual rivalry (such rivalry was experienced during the test) acts as a further hindrance to exact fusion.
Fig. 11 (Ogle, Mussey, and Prangen). Influence of red-green glasses for different degrees of peripheral fusion on fixation disparity.

However, the red-green glasses on the second subject had only a small effect on the results obtained, and almost no rivalry was experienced.

Effect of lenses. Because the change in fixation disparity with forced convergence or divergence is probably associated with the convergence-accommodation reflex, similar changes might be expected when the stimulus to accommodation was also changed, as, for example, when spherical ophthalmic lenses are placed before the eyes. Such a
change has been reported in the displacement of the longitudinal horopter as determined by the nonius method, when plus lenses were worn by the esophoric observer. Certainly the problem being studied would not be complete without such a consideration.

The procedure was to obtain data for the curves for the fixation disparity with forced changes in the convergence while spherical lenses are placed before the two eyes, for both distant and near vision.

NEAR-VISION TEST

Instrumentation. For the near-vision tests new instrumentation was necessary. A light box with a transparency plate in front was used instead of the projector lanterns and screen. Figure 12 illustrates the apparatus schematically. The features are essentially the same as those for the distant-vision apparatus, and no further description is necessary.

The fixation distance was 29 cm. (3.4
Fig. 12 (Ogle, Mussey, and Prangen). Perspective drawing of apparatus for measuring fixation disparity at near visual distances.

For distant vision, three sets of data were obtained: with the usual or with no refractive correction, and with supplemental lenses of +1.0D. sph. and —1.0D. sph. before both eyes. In each case the added sphere caused a displacement of the curves. As would be expected, the fixation disparity changes in the divergent direction with plus spheres, and in the convergent direction with minus spheres, which is in the direction that the phoria would also tend to change. The addition of the plus spheres in both cases blurred the vision somewhat, but not sufficiently to prevent data being taken, although the sensitivity was reduced.

diopters). If the subject had adequate accommodation, supplemental lenses of +2.0D. sph. and —2.0D. sph. were used, while if not, as in beginning presbyopia, supplemental lenses of +2.0D. sph. and +4.0D. sph. were used.

Characteristic curves were obtained, showing the marked influence of the stimulus to accommodation, and of the probable accommodation which took place, on the fixation disparity. Figures 13 and 14 show results of two subjects, characteristic of the two types.

It is of special interest to derive from these curves the various combinations of spheres
Fig. 13 (Ogle, Mussey, and Prangen). Effect of spherical lenses on the fixation disparity-convergence curve for visual distances of 2.5 meters and 29 cm.

and meter angles of convergence (prism power) each of which results in a given fixation disparity, especially a zero disparity, for then the cortical images would be exactly superimposed. Examples of such derived data are illustrated in Figure 15, for the two subjects for both distant and near vision.

In these graphs the abscissa represents the lens power and the ordinate the forced vergence—convergence positive and divergence negative. The values for forced vergence are measured from the meter angles of convergence corresponding to the distance of the target. Some inaccuracy cannot be avoided in selecting the place where a given
Fig. 14 (Ogle, Mussey, and Prangen). Effect of spherical lenses on the fixation disparity-convergence curve for visual distances of 2.5 meters and 29 cm.

curve in the original graph intersects the ordinate of a given fixation disparity. However, the results are not much in error.

The average slope of these lines is a measure of the comparative influence of prisms and lenses on fixation disparity and the convergence-accommodative relationship. For the two subjects illustrated here about 0.6 to 0.8 meter angle of convergence (3 to

tainly this could be taken as the condition of no muscular imbalance and perfect fusion, and as such it would be desirable. As far as the spherical lenses are concerned, it appears that when the subject wears the proper refractive correction the fixation disparity is small, if not actually zero.

The deficiency in the experimentation reported here lies in the fact that the actual
Fig. 15 (Ogle, Mussey, and Prangen). Derived data from Figures 13 and 14 showing comparative influence of prisms, forced vergence, and spherical ophthalmic lenses.

4 prism diopters) has the equivalent effect on fixation disparity of 1 diopter of lens power before the two eyes.

The approximate parallelism of the lines in these derived graphs certainly can be taken as evidence that the fixation disparity is a specific measure of the stress of muscle imbalance during fusion. The approximate parallelism of the lines indicates also that the addition of the spherical lenses has caused in the main a displacement of the curves, that is, has added a constant factor.

At this time it is not possible to attach special significance or functional importance to the "zero" disparity line, although certainly

state of accommodation in any given combination of lenses or prisms can only be presumed from the presence or absence of blur (loss of visual acuity). Reliance was placed on previous experimentation by one of us, which showed that the maximal change in accommodation with prism vergence was of the order of ±0.25 diopter, and on the literature, for the statement that the accommodation changes only very slightly for forced convergence or divergence except near the limits.

COMMENT

A fixation disparity can be measured in most subjects who show a heterophoria, re-

gardless of the type of fusion detail used in the target. This means, in general, that the retinal images of the point of fixation do not fall exactly on corresponding points.

Although ideally the fusion compulsion reflex strives to direct the pointing of the eyes so that the images fall as nearly as possible on corresponding retinal elements, it may only be able to keep the images within Panum's areas of fusion because of innervations or mechanical stresses which make up muscle imbalances. Thus the two cortical images arising from the two eyes will be slightly displaced or slipped with respect to each other.

By and large the direction of the fixation disparity is the same as that of the hetero-phoria, although apparently not correlated quantitatively with it, probably because the phoria is a phenomenon of the disassociated eyes. Fixation disparity *a priori* need not always be associated with a phoria. The stresses of dynamic muscular balance active during actual fusion may be the result not only of mechanical and tonic neuromuscular effects but also of functional innervations, all of which would not necessarily be present when the eyes are disassociated.

Occasionally, the initial fixation disparity is found in the direction opposite to the phoria, and generally this occurs in the case of a small esophoria which nevertheless exhibits a divergent deviation. The possible influence of "instrumental convergence" must not be excluded in the phoria measurement.

The subjects seem to fall into two more or less distinct groups according to the way in which the fixation disparity (cortical image slip) changes with forced convergence and divergence of the eyes. In the first group, the deviation increases with the degree of forced convergence, while in the second, the fixation disparity remains nearly constant with the degree of forced convergence or divergence, except near the limits of the fusional amplitudes. From one point of view these data indicate that in the

first type, fusion is more loosely held and the cortical images are more liable to slipping than in the second type, in which the fusion is more tightly held until the limits of fusional amplitudes are reached.

The existence of a more or less constant fixation disparity in the second type is difficult to account for. In a tightly held fusion, the second type of curve would be expected, but with the greater part of the curve coinciding with the abscissal axis, that is, with the fixation disparity zero. Only near the limits of the fusional amplitudes would there be a sudden change in the curve. The measurements of the fixation disparity as the fusion details are confined more and more peripherally constitute a crucial experiment. Otherwise, it might be argued that the constant deviation in the second group might be the result of an adapted change in the sensory subjective direction, in the same sense of an anomalous correspondence, developed by a constant fixation disparity under the influence of a neuromuscular tension.

The better explanation for these results is that the stress set up in the accommodative-convergence relationship produced by the prisms differs greatly with different individuals. Here two groups could be differentiated. In the first, a real stress is caused by the prisms, in an effort to resist the forced convergence. In addition to these stresses, there must be those manifested by the phoria. In the second group, the disproportion between the accommodation and the convergence due to the prisms introduces little or no additional stress at all; there is practically *no resistance to the prisms*, as though the accommodation and convergence relationship was exceedingly elastic, until the degree of convergence or divergence becomes great. Thus, in spite of the forced convergence caused by the prisms, only those stresses manifested by the phoria remain as the sole source for the ocular deviation. Hence, the fixation disparity would tend to remain constant. It would tend to be constant for a given pattern of fusion detail and only

secondarily to be influenced by a change in phoria with convergence.

Since the accommodative-convergence relationship is affected by lenses, which change the stimulus to accommodation, as well as by prisms, the fixation disparity is changed by lenses. In general it appears that the fixation disparity-prism vergence curves are displaced laterally, as though the lenses merely added a constant equivalent prism vergence change. The magnitude of this equivalence is about 0.6 meter angle (3.5 to 4 prism diopters) to 1 diopter lens power, although in one case of probable convergence insufficiency this was only 0.2-meter angle (1.5 prism diopters) to 1 diopter lens power.

These results show that fixation disparity is an indication, if not an actual measure, of the muscular imbalance when the images in the two eyes are fused. The magnitude of the fixation disparity, however, will depend not only on the stress of that muscular imbalance but also on the strength of the fusional reflex processes.

These results also suggest that the therapeutic results from the prescription of prisms would be different for the two groups of subjects as well as in specific cases. In the first they might prove helpful, in the second not at all. One could argue, however, that a much tighter fusion exists in the second group than in the first.

The interpretation of the prism vergence or fusional amplitude tests should be different for these two types of subjects.

ANTISTINE: A STUDY OF ITS TOXICITY ON TOPICAL APPLICATION TO THE EYE*

T. F. SCHLAEGEL, JR., M.D.

Indianapolis, Indiana

Antistine hydrochloride is a relatively new antihistaminic available for topical application to the eye. The oral use of such drugs as Benadryl and Pyribenzamine for the ocular symptoms of allergy has been disappointing.[1] The probable explanation is that insufficient drug reaches the site of the allergy.[2] Antistine, developed in an attempt to overcome this disadvantage, gives promise of symptomatic relief.[1] Since Antistine was the only antihistaminic commercially available for topical application to the eye at the time of these experiments, this study was limited to Antistine.

Clinical trial has not demonstrated any unusual reactions. Occasionally conjunctival congestion occurs and rarely an allergic reaction may be seen.[2a, 2b]

Recently Grant and Loeb reported on the toxicity of several different antihistaminics on the rabbit eye.[3] They studied the approximate maximum concentration at which no alteration in the rabbit cornea occurs, as shown by examination with the slitlamp, after a single drop of solution. For Antistine hydrochloride this concentration was 1.5 percent. At slightly higher concentrations, a temporary keratitis epithelialis develops. At still higher concentrations, corneal edema and loss of epithelium occurs. They found from the subjective standpoint that 0.75 percent Antistine produced the same discomfort as 0.5-percent tetracaine (Pontocaine) hydrochloride in human eyes. By altering the pH of the solutions, it was found that the discomfort was not attributable to excess acidity or alkalinity. None of the drugs produced anesthesia on the application of a single drop.

Recently Hurwitz gave the most comprehensive report of the clinical use of 0.5-percent Antistine. He found that 42 of 50 patients with various external ocular allergies obtained significant symptomatic relief.[1]

CHEMISTRY

Antistine hydrochloride[†] is a synthetic preparation bearing the chemical name of 2-phenyl-benzylaminoethyl-imidazoline hydrochloride. The structural formula is as follows:
The crystals are white, odorless, and have a bitter taste. Solutions for ocular application originally contained the sulfate salt and it is this product upon which Hurwitz reported.[1] It is now made as the hydrochloride in 0.5-percent concentration with a pH of 6.94 which is close to the pH of tears (7 to 7.5).[4] It is made as an isotonic buffered solution of the following formula:

Antistine hydrochloride	0.50
Boric acid powder U.S.P.	1.20
Sodium carbonate anhydrous	0.05
Potassium chloride C.P. anhydrous	0.15
Distilled water q.s.	100.00

According to Bourquin, Antistine may be combined with other substances such as penicillin, zinc, argyrol, mydriatics, and miotics.[5]

PHARMACOLOGY

A common feature of antihistaminics is an antagonism of all of the major effects of

---

† Manufactured by Ciba Pharmaceutical Products, Inc.

histamine except its gastric secretory activity.[6a, 6b] They differ greatly in other respects. Some show an atropinelike action, while others exert a spasmogenic effect in moderate or higher doses. Certain ones augment the pressor effect of epinephrine, while others block or even reverse it. Landau and Gay in Dale tests (inhibition of guinea pig gut contractions) found that within one minute Histadyl, Bromothen, Chlorothen, Pyribenzamine, and Neoantergan completely counteracted five times as much histamine. Within one minute, Benadyl completely antagonized an equal amount of histamine, but Antistine was fully effective against only one half the amount of histamine.[7]

In experiments to counteract the effect of histamine intoxication and anaphylactic shock on guinea pigs, Antistine was again found to be the weakest of the antihistaminics tested.[8] However, no parallel existed between effectiveness against histamine in guinea pigs and their effect against human allergy.[9] Antistine is used systemically in doses larger than that of other compounds (100 mg. tablets). It was found by Gay and others to be the most effective antihistaminic against urticaria and angioneurotic edema and against dermatitis and pruritic conditions of various etiology, and it produced the smallest number of side effects (18 percent).[9]

Despite conflicting reports the consensus is that antihistaminics influence allergic symptoms by a specific antagonism of the pharmacologic effect of histamine.[6a, 10] Although there is no proof of the mechanism of action, the current belief is that they compete with histamine for the same receptor cell, displacing histamine from its point of action.[6a]

EXPERIMENT 1

Effect of Antistine on normal cornea. Since clinical trial has demonstrated an apparent lack of damage to the cornea, it was thought that a preliminary test on a small series of rabbits would be adequate before a more

careful determination of its effect on the normal human cornea. It was found that staining with fluorescein was no more common in eyes treated repeatedly with 0.5-percent Antistine than in normal untreated rabbit eyes.

Effect on human cornea. Ten medical-student volunteers were selected. Both eyes of each were flushed with fluorescein and examined with the slitlamp prior to the experiment. The effect of 0.5-percent Antistine hydrochloride was compared with that of a buffered isotonic control. At intervals of one-half hour for 12 times two drops were instilled above the limbus of each eye. Antistine was used in the right eye and the control solution in the left eyes. The formula for this buffered isotonic control was:

Sodium carbonate anhydrous	0.016
Potassium chloride	0.028
Boric acid crystals	2.500
Distilled water q.s.	100.000

The pH of this solution was 5.80 and was raised to 6.94 by the addition of a few drops of concentrated sodium hydroxide. The experiments of Friedenwald and Buschke have shown that wound healing in the corneal epithelium occurs at a pH from 4.5 to 9.5.[11]

Subjective comments. Burning for a minute or two occurred after application of drops of both Antistine and the control solution but was slightly more pronounced with Antistine.

Gross objective findings. The characteristic reaction to the frequent instillation of drops was a mild to moderate congestion, mainly bulbar in distribution. It was slightly greater in the right eyes receiving Antistine.

Biomicroscopy. At the end of the day, both eyes were again flushed with fluorescein and examined with the slitlamp. In only 1 of the 10 volunteers (number 6) was any change noticed. This volunteer was an agitated "expectant" father. In the right eye treated with Antistine there were small punctate points joined to produce horizontal linear streaks below and nasal to the pupil. In the left eye treated with the control solution a

superficial punctate area, about 3 mm. in diameter, was found near the limbus at the 8-o'clock position. Since the staining was bilateral and more severe in the control eye, it was felt that some intercurrent factors were involved.

Summary. A 0.5-percent solution of Antistine hydrochloride instilled at half-hour intervals for 12 times in 10 human eyes produced no discernible corneal damage attributable to the drug. Bulbar congestion occurred in both eyes, but was slightly greater in those treated with Antistine; the subjective sensation of stinging was slightly greater in the Antistine-treated eyes.

EXPERIMENT 2

The effect of Antistine upon reëpithelization of the denuded rabbit cornea. It is generally known that agents that are noninjurious to the cornea and conjunctiva of the

the fingers. The epithelium was then completely removed by abrasion with sterile gauze. The completeness of denudation was checked by instillation of 2-percent sodium fluorescein followed by a gentle flushing from an eye dropper with a solution of penicillin-G potassium, 2,500 units to the ml., which does not delay healing.[13] Two drops were instilled above the limbus of each cornea five times a day.

In Group I the right eyes received 0.25-percent Antistine, and the left eyes, the control solution.

The right eyes of Group II received regular 0.5-percent Antistine, and the left eyes, the control solution.

The right eyes of Group III were given 1-percent and the left eyes 2-percent Antistine.*

TABLE 1

THE DAY OF THE EXPERIMENT ON WHICH DENUDED RABBIT CORNEAS HEALED WHILE UNDER TREATMENT WITH BUFFERED ISOTONIC CONTROL OR WITH VARIOUS STRENGTHS OF ANTISTINE SOLUTION

Drug		Day of Experiment													Average
		4	5	6	7	8	9	10	11	12	13	14	15	etc.	
Group I	Control		2	3	3	1									6.3
	Antistine (0.25%)	1	3	1	4										6.3
Group II	Control			2	4	3	1								7.3
	Antistine (0.5%)		1	1	4	2		1			1				7.9
Group III	Antistine (1%)					3	2	1	1			2			10.3
	Antistine (2%)						3			1		5			12.5

rabbit are equally or even less irritating to that of the human eye and that the cornea is an excellent medium to ascertain information relative to the local tissue effect of drugs.[14]

To test the possible toxic effects of Antistine upon the rabbit cornea more carefully, 30 young adult pigmented rabbits with normal eyes were selected and divided into 3 groups of 10 rabbits each. Four-percent cocaine was used for anesthesia and to loosen the epithelium. To expose and fix the eyes, they were proptosed and held between

Complete denudation has been used frequently.[13-15] Other methods such as disc denudation outlined with a cork borer,[15] strip denudation outlined with double-bladed corneal knife,[16] and needle prick have been employed.[11] De Roetth objected to complete denudation because he felt that it was diffi-

* Supplied through the courtesy of Dr. F. L. Mohr and Ciba Pharmaceutical Products, Inc., Summit, New Jersey. All of the Antistine solutions were formulated to be isotonic and buffered with a constant pH of 6.94 so the only variable was the drug used. The 0.25-, 0.5-, and 1-percent strengths were made as the hydrochloride but the 2-percent strength had to be made up as the sulfate since the hydrochloride is not sufficiently soluble.

cult to be certain that one is producing constant damage.[17]

This objection has validity and is the reason for our separating Group I from Groups II and III in Table 1. The reason for this was that the day following the denudation it was obvious that the first 10 rabbits (Group I) had not been denuded as completely as the last 20, for in the first 10 the epithelium had already begun regeneration but had not in the last 20 rabbits. That this difference was not due to the drugs employed was indicated by the fact that the left eyes of Group I and the left eyes of Group II both received the same control solution. That the completeness of denudation was reliably equal within the groups was indicated by observation and by standardization upon previous rabbits and by frequent repetition of the same maneuver.

Results. The regeneration in uncomplicated cases is easily followed since the crescent of reëpithelized cornea at the limbus stands out brilliantly clear and normal against the greenish stained haze of the denuded area. The eyes were examined daily by staining with fluorescein and flushing gently with a solution of penicillin. Obvious secondary infection was rare. Only one rabbit in Group I was discarded because of delay in healing from secondary infection, while one rabbit in Group III died of intercurrent disease.

Group I. Except for the one discarded rabbit the corneas reëpithelized from the 4th to the 8th day with an average healing time of 6.3 days with both the 0.25-percent Antistine and the isotonic buffered control.

Group II. There was no significant difference in the healing time of the right eyes treated with regular clinical 0.5-percent Antistine hydrochloride (average 7.9 days) and the left eyes treated with the control (average 7.3 days).

Group III. Healing in Groups I and II was complicated only by a faint diffuse haze which was considered the result of super-

ficial stromal damage at the time of denudation. The use of stronger strengths of Antistine caused greater conjunctival congestion, a definite delay in healing, and other evidence of corneal damage. This delay with 1-percent Antistine hydrochloride was moderate (10.3 days) and the corneal damage

Fig. 1 (Schlaegel). Grossly relucent and vascularized rabbit cornea that had been treated with 2-percent Antistine. This cornea had apparently healed as indicated by lack of gross staining with fluorescein.

was moderate with superficial vascularization.

The healing time with 2-percent Antistine sulfate was pronouncedly increased (12.5 days) and the corneal damage was severe. In five of the rabbits, most of the cornea not protected by the nictitating membrane was rendered grossly relucent, densely vascularized, and very slow to heal (fig. 1).

Although clinically healed on the 15th day, microscopic sections revealed that the stroma was covered not by epithelium but by a hyaline membrane 1 to 2 times as thick as Descemet's membrane (fig. 2). Van Gieson stain indicated that the hyaline membrane was modified superficial stroma.

Summary. The use of Antistine five times a day on completely denuded rabbit corneas demonstrated that the 0.25- and 0.5-percent solutions do not delay healing over that of the control solution, but that the 1-percent and especially the 2-percent strengths are definitely toxic, resulting in delayed healing and vascularized scars.
Fig. 2 (Schlaegel). Microscopic sections revealed that the cornea had not become reëpithelized, but that the superficial stroma had developed a hyaline membrane. Degeneration, vascularization, and cellular infiltration of anterior two thirds of stroma.

EXPERIMENT 3

Effect of Antistine on the size of pupil and upon accommodation. Since some of the antihistaminics demonstrate an atropinelike, spasmogenic, or adrenergic response, it was felt necessary to check the pupil and ciliary body for signs of effect. Harris, McGavack, and Elias found that Benadryl applied topically to the bulbar conjunctiva in 0.5-percent aqueous solution produced a moderate mydriasis of readily measurable proportions which appeared within 15 minutes and became maximum within one hour.[18] The capacity for accommodation was simultaneously decreased. Benadryl enhanced the mydriasis of homatropine and lessened the miosis of eserine. However, no effect on the pupil was noted from the oral use of 400

mg. of Benadryl daily. In their studies of Antistine hydrochloride, Benadryl hydrochloride, Decapryn, Histadyl, Neoantergan, Pyribenzamine, Thenylene, and Thephorin, Grant and Loeb noted that only Benadryl hydrochloride had a noticeable mydriatic or cycloplegic effect.[3] Using Benadryl, Antistine, and Pyribenzamine, von Sallmann found that only Antistine did not weaken the miotic action of di-isopropyl fluorophosphate.[19]

Methods. Under constant conditions of illumination, the apparent size of the pupils of the 10 human volunteers previously mentioned was measured before and after the day of drop instillations. Reading was permitted during the experiment. Using a Prince rule with Duane line for test object the nearpoint of accommodation of each eye was checked 10 times both before and after the experiment by bringing the test object toward the subject to the point of blur. Since only the relation between "before" and "after" was desired the total cycloplogic error was not determined and glasses were worn only if desired.

Results (Pupil). Table 2 clearly demonstrates an absence of effect on the pupil. *(Accommodation).* Table 3 gives the results of the average value of the 10 measure-

Standard Deviation	3.5	2.4	2.5	2.1

but statistical analysis indicates that none of these differences is significant.

Summary. Antistine hydrochlroide (0.5-percent) applied as drops 12 times in one day to the eyes of 10 human volunteers failed to affect the size of the pupil or the accommodation.

COMMENT

Experimental studies of the toxicity of antibiotics on the cornea indicate that many of them, especially in the powder or ointment form, produce some damage.[12, 14-16,20] It has also been shown that anesthetics and antiseptics commonly employed in ophthalmology are even more toxic to the cornea.[13, 21, 22] Since Antistine hydrochloride solution in 0.25- and 0.5-percent strengths did not produce corneal damage in these experiments, Antistine as commercially supplied (0.5-percent solution) should be a safe drug to add to our armamentarium.

GENERAL SUMMARY

1. Antistine hydrochloride (0.5-percent) instilled repeatedly in 10 human eyes produced no discernible corneal damage. Bulbar congestion and subjective stinging were slightly greater with Antistine than with the control solution.

2. The use of Antistine on completely denuded rabbit corneas demonstrated that 0.25- and 0.5-percent solutions do not delay healing longer than does a control solution, but that the 1-percent and especially the 2-percent strengths are definitely toxic.

3. Antistine hydrochloride (0.5-percent) applied as drops 12 times in one day to the eyes of 10 human volunteers failed to affect the size of the pupil or the accommodation.

CONCLUSIONS

These experiments indicate that 0.5-percent Antistine hydrochloride is not toxic to the cornea and does not affect the pupil or accommodation.

THE EFFECT OF DICUMAROL ON THE VISUAL FIELDS IN GLAUCOMA*

A PRELIMINARY REPORT

WILLIAM P. McGUIRE, M.D.
Winchester, Virginia

The problem of progressive loss of visual field following a successful filtration operation in glaucoma is one that has plagued ophthalmologists for years. The general consensus seems to be that these changes are due to an irreversible vascular process which is set up while the tension is above normal limits and has progressed sufficiently so that when the tension is reduced, either by surgical or medical means, there is no regression, but apparently a continued progression of the vascular process.

As far as can be determined, no completely satisfactory pathologic observations have been made on the ocular vascular system in early cases of chronic simple glaucoma. Duke-Elder[1] states that there is a vascular stasis and quotes three individual case reports by Levinsohn, 1908, Ronne, 1913, and Hanssen, 1918, in which all showed evidence of circulatory stasis and vascular lesions, either of periphlebitis or endophlebitis of the episcleral or vortex veins, with areas of leukocytic infiltration.

Knapp,[2] in reporting on cases of atrophy of the optic nerve with cupping and low tension, states that "atheromatous carotid arteries cannot alone cause this descending atrophy, but the condition must be caused by simultaneous circulatory disturbances in the optic nerve from arteriosclerotic vascular changes."

Best[3] called attention to the fact that arteriosclerotic changes in the small nutrient vessels may damage the optic nerve, while Siegert[4] and von Stief[5] believed that the cause of optic atrophy in cases of "pseudoglaucoma" are the result of arteriosclerotic changes in the vessels supplying the optic paths.

Gradle,[6] in discussing glaucomatous cupping and atrophy of the optic nerve in cases where the tension was never found to be elevated, held that the condition begins as a low-grade neuritis limited to the anterior third of the optic nerve, the vessel-bearing portion, and leading to an absorption of the nerve fibers, producing the cavernous changes in the nerve described by Schnabel.[7] Lagrange and Beauvieux[8] found sclerosis and obliteration of the small nutritive vessels of the nerve in several cases of primary glaucoma.

Loewenstein[9] demonstrated changes in the walls and thromboses in the small vessels of the optic nerve, producing cavernous degeneration and sclerotic plaques. He concluded that the degenerative changes found in the nerve in glaucoma are the result of vascular damage with impairment of nutrition rather than the effect of increased intraocular pressure.

It is interesting to note that the recent studies of Putnam[10] and his co-workers on the etiology of disseminated sclerosis present some evidence that vascular thrombosis has a definite bearing on the formation of the plaques found in nerve tissue in this disease. This group has recently treated a series of cases of acute disseminated sclerosis with dicoumarin and report encouraging results in those cases which are characterized by remissions and exacerbations.

Rintelen[11] has described the histologic findings in cases of arteriosclerotic atrophy of the optic nerve. He believes that sclerosis of the central retinal artery has little or no effect on the nerve and that the damage in these cases is due to sclerosis of the small nutrient vessels. Vail[12] states, "It is entirely probable that vascular disease of the nerve may account for the progress of cupping,

---

1095

atrophy, and field changes that frequently occur after the ocular hypertension has been quite controlled in true glaucoma, especially in the aged."

In view of these facts and hypotheses it would seem that the most reasonable explanation for the progressive field changes in chronic-simple glaucoma is arteriosclerotic changes in the nutrient vessels of the optic nerve. These changes may involve slowing of the blood stream, narrowing of the lumen of the vessels, formation of atheromatous plaques in the endothelium, and formation of mural thrombi.

In searching for some method to treat these patients, many of whom seem to be in desperate straits, it was believed that a vasodilator might be of benefit if the vasodilatation could be prolonged. Further, it seemed that a drug with anticoagulant properties which would inhibit the formation of thrombi might possibly be of value in the treatment of these cases. The only drug which met both of these requirements was dicumarol.

Schofield,[13] in 1924, and Roderick,[14] in 1929, reported on hemorrhage disease in cattle following ingestion of spoiled sweet-clover hay. In 1939, Link[15] and his associates isolated and crystallized the active principle in spoiled sweet-clover hay that was responsible for this disease of cattle. Since that time a great number of experimental and clinical investigations have been made on 3,3'-methylenebis (4-hydroxycoumarin), better known as dicoumarin or dicumarol.

Meyer, Bingham, and Axelrod[16] reported that the administration of the chemical, either orally or intravenously, is succeeded by a protracted prolongation of the prothrombin time and coagulation time. This effect follows an initial latent period of 24 hours following administration of the drug. In therapeutic amounts no untoward symptoms were produced but excessive quantities produced spontaneous hemorrhages and fatalities in dogs.

Bingham, Meyer, and Pohle[17] first noted

that the most constant pathologic change produced by the substance is a widespread dilatation of capillaries, arterioles and venules, and this finding has been confirmed by Wright and Prandoni,[18] Bollman and Preston[19] and Townsent and Mills.[20] It is of interest to note that this vasodilatation occurred in animals whether they died from overdose of the drug or were destroyed for study following therapeutic dosages.

In treating patients suffering from arteriosclerosis obliterans or thromboangiitis obliterans with dicumarol, Wright and Prandoni[18] noted an increased tendency to bleed at the site of ulceration and attributed it to the dilatation of minute vessels. Allen, Barker, and Waugh[21] believe that something in the body is necessary for the action of dicoumarin because if the drug is added to drawn blood, the prothrombin time is not affected. The bleeding time is not affected by the clinical use of the drug but the sedimentation rate is routinely increased.

The method used in administration of the drug in the cases to be reported consisted in hospitalizing the patients and, on the first day of hospitalization, the administration of 300 mg. of dicumarol by mouth.

Routine determination of the prothrombin time, according to the method of Quick[22] was started on the second day in the hospital and carried out daily thereafter. According to this method the normal prothrombin time runs around 11 to 13 seconds. By the administration of dicumarol the prothrombin time was elevated to between 35 to 45 seconds and maintained at that level during the period of hospitalization. The amount of dicumarol to be given each day is determined by the reported prothrombin time of that day. On the average it was found that after the initial dosage of the drug a daily dosage of 100 mg. was sufficient to maintain the desired level in the blood, although on occasion the dose had to be decreased or increased for a day or so.

It is of interest to note in this connection that, if there appears to be some danger of

hemorrhage, the prothrombin time can be reduced dramatically by the intramuscular injection of 50,000 units of penicillin. This will reduce the prothrombin time but will not prevent it being raised again to the desired level by the administration of dicumarol, while the intravenous use of vitamin K will not only reduce the prothrombin time but keep it at low levels for several days in spite of the continued use of the anticoagulant.

Of the nine cases to be reported in this paper, dicumarol was initially administered for a period of two weeks only. However, several patients have had a second course of the drug because, while some improvement was noted after the first course, it was felt that further improvement was desirable and consequently further treatment was advised.

The first case reported was perhaps the most dramatic of all. After the first course of dicumarol, from which there was a most striking, and to me unbelievable, response, the fields held well for a period of 10 months. At this time it was noted that there was again a marked lower nasal field cut to within 10 degrees of fixation. The patient was given a second course of the drug and one month after this the field had again become almost normal while a month later it was within normal limits and has remained so until the present, 8 months after the last course of dicumarol.

This quite naturally brings up the question as to whether it is necessary to give repeated courses of the drug and at what intervals these should be given, or whether, as in the case of some patients who have suffered thrombosis of the coronary artery, a maintenance dose of the drug should be given for some months or years. I am not prepared to answer this question definitely at the present time, although I do have three elderly patients with advanced field changes on a maintenance dose at this time. These patients all had increased intraocular pressure which was reduced by operation, but I believe that the field changes in them were more characteristic of an arteriosclerosis of

the vessels supplying the optic pathways than of those which we ordinarily associate with glaucoma. It is too early to speculate what the outcome will be in these elderly patients for if, after further study, this therapy proves to be of value in treating the visual changes in long-standing glaucoma it is my belief that the older patient with advanced field changes, due in all probability to arteriosclerosis, will prove to be the most intractable type of case for such treatment.

Again, although I have not yet carried out such a procedure, I have the feeling that, if dicumarol proves to be of value in these cases, probably the most advantageous use of the drug would be its long-continued administration over a period of years with weekly checks on the prothrombin time after the blood level is finally stablized.

CASE REPORTS

Case 1. W. G., aged 44 years. This Negro was first seen on December 12, 1944, complaining of early presbyopic symptoms. He stated that the vision in the right eye had been failing for some years but he thought the left eye was all right and that all he needed was some reading glasses. There was no history of pain or congestion in the eyes at any time. Vision was: O.D., hand movements at one foot; O.S., 20/30.

External examination was negative with the exception of the pupils which were semidilated and reacted poorly. The media were clear while the fundi showed a minimal arteriolar sclerosis and a deep cupping of each disc of the glaucomatous type, the pallor of the nervehead being more marked in the right eye.

The vision in the right eye could not be improved while in the left it was improved to 20/20 by +0.5D. sph. Intraocular pressure was O.D., 29 mm. Hg; O.S., 42 mm. Hg (Schiøtz). No visual field was obtainable in the right eye while that in the left eye revealed a marked defect in both the upper and lower nasal quadrants. Pilocarpine (2 percent) was ordered to be instilled four times daily and the patient asked to report in two weeks. At this time the tension was O.D., 25 mm. Hg; O.S. 35 mm. Hg; and operative intervention was advised for the left eye.

On January 7, 1945, a modified Lagrange operation was performed on the left eye. The postoperative course was uneventful, and one month after the surgical procedure tension was O.D., 25 mm. Hg; O.S., 17 mm. Hg. From that time until the present the tension in the left eye has never been above 17 mm. Hg nor below 13 mm. Hg on repeated examinations.

However, on March 31, 1945, almost three months after operation, the field in the left eye showed a good deal more contraction, and three months later the contraction was even more marked. Following this there was a more gradual contraction of the field until December, 1946. At this time the best corrected vision in the left eye was 20/30, but it should be emphasized that at no time during the observation of this patient had the blindspot showed any variation from normal.

weeks later, on November 15th, the field had again returned to normal limits and the corrected vision was 20/20. He was last seen in February, 1948, and the field was holding well.

Case 2. M. W. P., a white man, aged 60 years, was first seen in October, 1936, when he stated that he had lost the sight in the right eye four years previously. He had not consulted a physician and came in merely to see about getting some reading glasses.

Fig. 1 (McGuire). Case 1.

Fig. 2 (McGuire). Case 1.

Dicumarol therapy was ordered on December 12, 1946, and the patient was kept on the medication for 10 days. He was seen again on January 11, 1947, and the field was found to be much improved. Two months later, on March 15th, three months after the dicumarol therapy, he was again checked and the field found to be full in all meridians.

In June of 1947 the field remained normal and he was asked to report again in three months. On September 27, 1947, the field had begun to show a temporal contraction and a marked lower nasal quadrant cut to within 10 degrees of fixation. The blindspot remained unaffected and the best corrected vision was 20/25. At this time he was put on dicumarol for two weeks and on October 18, 1947, the field had shown marked improvement while four

There was no history of pain or inflammation in either eye. There was no light perception in the right eye while the vision in the left was 20/20.

The external examination was negative with the exception of the right pupil which did not react to light and was partially dilated. The media were clear. The fundi showed marked glaucomatous atrophy of the right nervehead and some shallow cupping of the left disc. There was a slight upper nasal contraction of the left field.

Intraocular pressure was: O.D., 48 mm. Hg; O.S., 35 mm. Hg. Pilocarpine was ordered for each eye and under this regimen the tension was reduced to: O.D., 30 mm. Hg, and O.S., 17 mm. Hg. No essential change was noted in the eyes until the middle of 1940, four years after the patient was

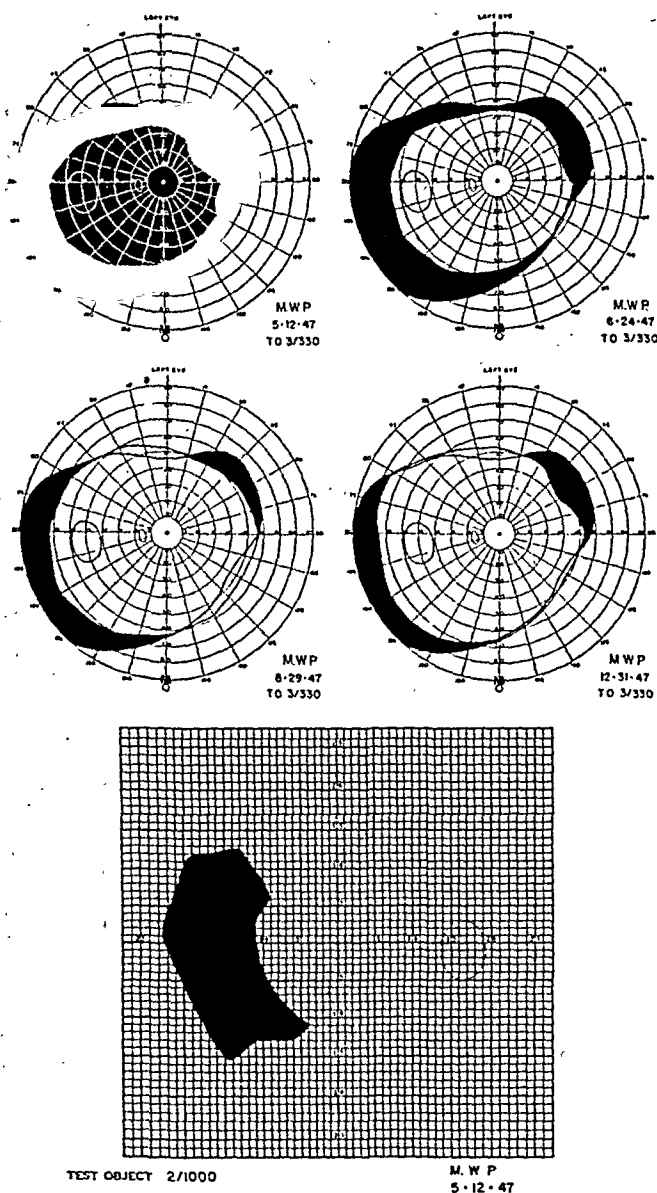
first seen, when, in spite of the continued use of miotics the tension began to rise slightly in the left eye. Between May and December, 1940, the tension varied between 17 mm. Hg and 35 mm. Hg in the left eye with a base curve which was showing a slow but constant increase. On December 31, 1940,


Fig. 3 (McGuire). Case 2.

a trephination was done on the left eye, following which the tension was reduced from 40 mm. Hg to 15 mm. Hg, in which neighborhood it remained for several years.

During late 1943, the patient developed an acute exacerbation of the glaucoma in the blind right eye and a complete iridectomy was performed by Dr. Louis S. Greene in January, 1944. This served to reduce the tension for only a few months and then the patient began to develop spontaneous hemorrhages from the iris in the right eye and the globe was enucleated in May, 1945. In the meantime the tension and the field in the left eye had been holding well. In August, 1946, it was noted that the field in the left eye had begun to show a little more

contraction and a 48-hour tension curve was done with the highest tension recorded at 22 mm. Hg (Schiøtz).

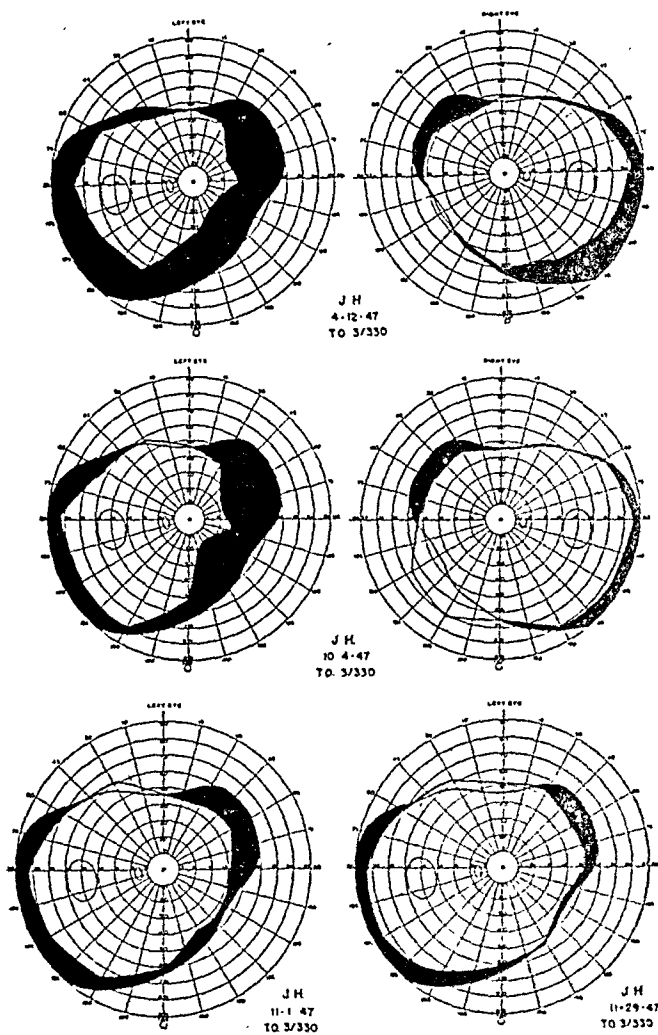
In May, 1947, the field was found to be more contracted and the blindspot definitely enlarged. Dicumarol therapy was advised and the patient entered the hospital for this therapy on May 15, 1947. He had two weeks on the drug and, on June 24th, it was noted that the nervehead was of better color and the field was improved. On August 29th the field showed continued improvement and the


Fig. 4 (McGuire). Case 3.

blindspot was about normal in size, while the fields were maintained at the same level on December 31, 1947.

In this case the central vision in the left eye has never been worse than 20/30, corrected, and, when the patient was last seen, it was corrected to 20/20.

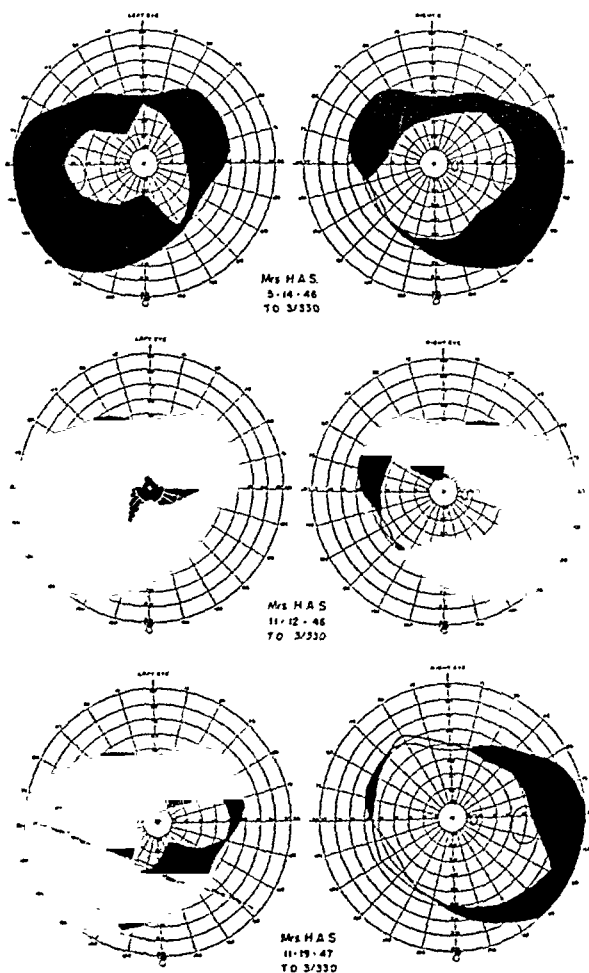
Case 3. J. L. H., a white man, aged 45 years, was first seen in August, 1944, when he came to the office for a change of glasses. There was no history of ocular trouble other than the usual presbyopic symptoms. The vision was 20/20 in each eye, corrected to 20/15 in the right eye and 20/15 in the left. The external examination was negative and the media were clear. The fundi were normal with
Fig. 5 (McGuire). Case 4.


Fig. 6 (McGuire). Case 5.

the exception of the left nervehead which showed a moderate pallor and a shallow cupping.

Intraocular pressure was: O.D., 17 mm. Hg; O.S., 29 mm. Hg. The right field was full while the left showed some upper nasal contraction, although this was not marked. The patient was placed on pilocarpine but the tension remained unchanged.

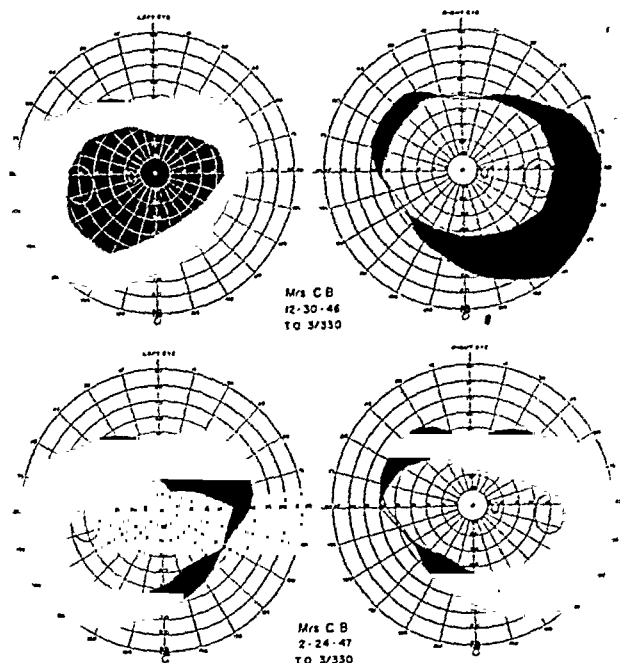
                                  6-25-47


Fig. 7 (McGuire). Case 6.

On December 2, 1944, a trephination was done on the left eye. Following this procedure the tension dropped to 6 mm. Hg but, within a month, had risen to 35 mm. Hg. Miotics were again ordered and the tension was slowly reduced to normal limits.

From June, 1945, until April, 1947, the patient did not report for a checkup and, when he finally was seen on April 12, 1947, he reported that his eyes had been comfortable but that he thought he needed more help in reading. At this time the corrected vision was 20/15 in the right eye and 20/25

in the left. The fundi showed no appreciable change. Tension was: O.D., 17 mm. Hg; O.S., 22 mm. Hg.

The left field showed more contraction. On October 4, 1947, the field showed even more contraction and the blindspot a marked enlargement. Dicumarol therapy was advised. The patient entered the hospital on October 8th and received dicumarol for two weeks. On November 1st, the field showed marked improvement and, on November 29th, slightly more improvement was apparent while the

blindspot had been materially reduced in size. At this time the corrected vision remained at 20/25 and the tension at 22 mm. Hg in the left eye. When last seen in April, 1948, the field and blindspot showed no appreciable change over a period of almost five months.
Fig. 9 (McGuire). Case 6.

Fig. 8 (McGuire). Case 6.

Case 4. G. W. M., a white man, aged 74 years, was first seen in April, 1944, with a vision of 20/200 in each eye, corrected to: O.D., 20/70; O.S., 20/20—. There was a nuclear sclerosis in each lens and a shallow cupping of each disc.

Intraocular pressure was: O.D., 29 mm. Hg; O.S., 40 mm. Hg, and there was a slight concentric contraction of the visual field in each eye. The patient was ordered to use miotics and was followed in the office at intervals. By April, 1947, the tension had risen to 40 mm. Hg in each eye and the fields showed more cut in each eye.

In May, 1947, a flap sclerotomy was done bilaterally and dicumarol was administered for two weeks. Following operation the tension has re-

mained within normal limits and in October, 1947, the field showed marked improvement. At the last visit, October, 1947, the nuclear sclerosis had increased markedly and the best corrected vision was 20/100 in each eye.

In spite of being advised to return for periodic checkups, this patient, who lives at a considerable distance, has not returned and I have, unfortunately, lost contact with him.

There was no appreciable change in conditions until March, 1940, when the patient was hospitalized for a 24-hour tension curve. During this period and, in spite of the continuance of pilocarpine as before, the tension was found to be elevated in the early

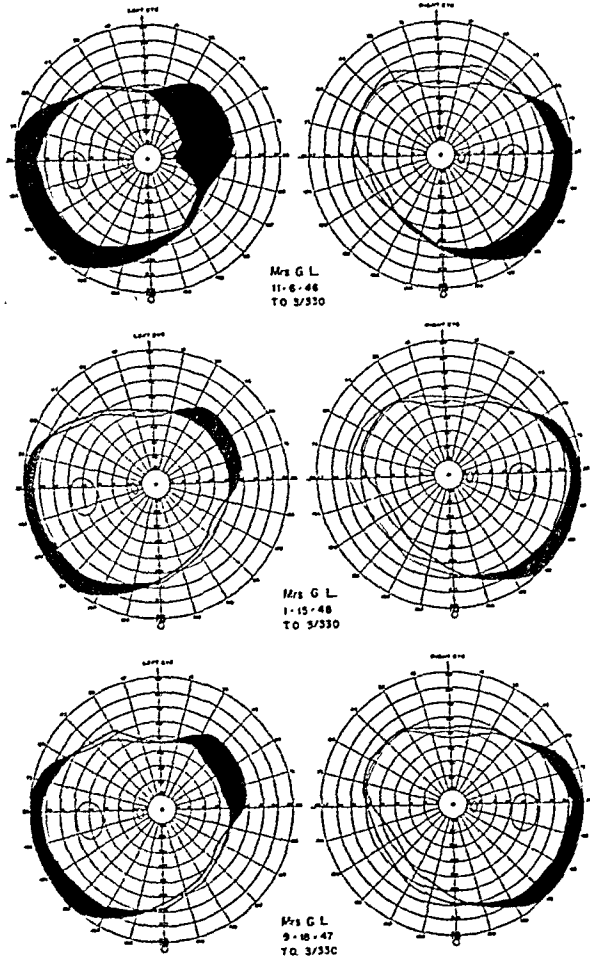

Fig. 11 (McGuire). Case 8.

Case 5. Mrs. H. A. S., aged 67 years, white, was first seen in June, 1945, when she stated that she thought she needed a change of glasses. Upon questioning she stated that for several years she had noticed that she could not see objects to the side of her direct line of vision but that she had paid no attention to this phenomenon.

Vision in the right eye was 20/50—, corrected to 20/20; in the left, 20/70—, corrected to 20/40—. The media were clear and the fundi revealed a Grade-2 retinal arteriolar sclerosis and a marked cupping of the glaucomatous type in each nerve, associated with an extreme pallor. Both visual fields showed a great deal of constriction, the left being more marked than the right. Tension was: O.D., 25 mm. Hg; O.S., 35 mm. Hg. Pilocarpine (2 percent) was prescribed four times daily.
morning hours to: O.D., 35 mm. Hg; O.S., 48 mm. Hg. Iridencleisis was performed on each eye with an interval of one week between operations. Immediately after operation the tension was reduced to O.D., 19 mm. Hg; O.S., 11 mm. Hg and, since operation, has never been found above 22 mm. Hg in either eye.

While the patient was still convalescent it was noted that the vascularity in each nervehead was improving, so much so in the left eye that the vessels on the left disc looked like a Medusa head of capillaries, and the color of the discs in general was much improved. When the fields were checked in May, 1946, two months after operation, they were found to be much improved, but by November 12th

of the same year they had again begun to contract. They remained in about the same stage until August, 1947, when the patient entered the hospital for dicumarol therapy which she had for two weeks.

On November 19, 1947, the right field had improved very strikingly while the left showed marked contraction with a central defect. At this time the corrected vision in the right eye was 20/20—, and in the left, 20/60 eccentric.

June, 1946, a bilateral iridencleisis was done. Since operation, the tension has remained within normal limits but, by February, 1947, the fields showed more contraction, particularly in the upper portion, while by June 25th of that year, the blindspots had markedly increased in size.

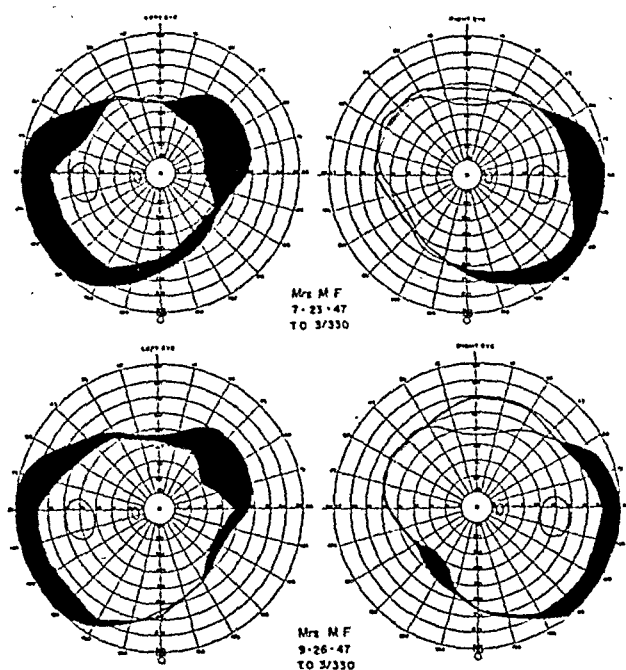
The patient was placed on dicumarol for two weeks and one month later the central fields had improved to some extent. On August 25, September


Fig. 12 (McGuire). Case 8.

Fig. 13 (McGuire). Case 8.

Case 6. Mrs. C. B., aged 73 years, white, was first seen in January, 1946, with a corrected vision of 20/20 in each eye. Tension was: O.D., 26 mm. Hg; O.S., 22 mm. Hg. There was a faint nuclear sclerosis in each lens and a shallow cupping with some pallor of each disc. The fields showed some slight bitemporal contraction and there was some enlargement of the blindspots. Roentgen examination of the skull was negative with the exception of calcified posterior clinoid ligaments.

In spite of the use of miotics the tension varied between 22 and 30 mm. Hg in each eye and in

24, November 5, 1947, and January 9, 1948, a progressive improvement was noted in both the peripheral and central fields. The corrected central vision in each eye has steadily become worse due to the development of lenticular opacities. This patient was last seen in April, 1948, when it was found that the fields and blindspots were virtually unchanged in the 3-month period.

Case 7. Mrs. G. L., aged 47 years, a white housewife, first presented herself on September 4, 1947, stating that she did not think she saw well enough

with the glasses that she was wearing. She had had them for several years. Her husband was a photographer and she had made a practice of helping with work in the developing room. She had noticed that recently, after working in the darkroom for several hourse, she would have a headache and pain in the eyes.

Vision in the right eye was 20/30—, and in the left, 20/40—, each correctible to 20/15—. The media

Fig. 14 (McGuire). Case 9.

were clear. The fundi were normal with the exception of the left disc which showed a very shallow cupping with a questionable pallor. Intraocular pressure was: O.D., 22 mm. Hg; and O.S., 26 mm. Hg.

Visual fields showed an upper nasal cut in the left eye and a slight concentric contraction temporally in both eyes with a beginning enlargement of the blindspot in the left eye. Two-percent pilocarpine was prescribed for each eye four times daily and, when the patient was next seen in early November, the tension was O.D., 19 mm. Hg; O.S., 22 mm. Hg. There was no change in the fields and the patient still complained of the same symptoms following work in the darkroom.

An iridencleisis was performed on the left eye on November 19, 1946, and on the right eye the following week. The postoperative course was uneventful and, upon repeated checks since operation, the tension in either eye has not varied from a low of 15 to a high of 19 mm. Hg. There was no
Fig. 15 (McGuire). Case 9.

material change in the fields through June, 1947, but at this time the best corrected vision had decreased to: O.D., 20/20; O.S., 20/25—.

Two months later, on August 23, 1947, the fields were unchanged from the preoperative appearance

but the left blindspot had enlarged slightly while the right was a little larger than normal.

Dicumarol therapy was advised and during the first two weeks in September the patient was in the hospital for a course of the drug. On September 18, 1947, the field and blindspots showed some improvement, while on January 15, 1948, the blindspots were normal in size and the only remaining peripheral field defect was a slight concentric contraction in the upper nasal quadrant of the left eye. At this time the corrected vision in each eye was 20/15—.

Case 8. Mrs. M. F., aged 52 years, white, was first seen in the office in June, 1945, at which time she complained of gradual loss of vision in the left eye. Vision in the right eye was 20/100 corrected to 20/15, while that in the left eye was 20/70—, unimproved. Tension was 19 mm. Hg in the right eye and 35 mm. Hg in the left eye. Nothing remarkable was noted in the examination other than a rather marked cupping and pallor of the left disc with some loss of field and a large Bjerrum scotoma above in the left eye. The patient was placed on miotics and the tension was found to be: O.D., 19 mm. Hg; O.S., 22 mm. Hg, when she was next seen several weeks later.

One year later, in spite of maintaining normal tension at every office visit the field showed more cut, while in March, 1947, there was an even greater defect in the field. At this time a flap sclerotomy was performed on the left eye and the patient was given dicumarol for two weeks. Following this the field improved somewhat but the tension in the left eye rose to 30 mm. Hg and remained at that level in spite of the continued use of miotics, also the blindspot increased in size. Consequently in October, 1947, an iridencleisis was done on the left eye followed by two additional weeks on dicumarol. In November, one month after operation, the tension was 19 mm. Hg in each eye and has remained at that level since, while at the same time the field showed considerable improvement. In January, 1948, the field was almost normal in all meridians and the Bjerrum scotoma has shown some improvement but the central vision has not been improved.

Case 9. Mrs. C. B. J., aged 36 years, white, was first seen on April 21, 1947. She stated that she had been born blind in the right eye and that, while she was still an infant, it had begun to enlarge. It had been enucleated because of pain by Dr. Louis S. Greene 10 years before I had seen her. She said that Dr. Greene had prescribed drops for the left eye and had cautioned her about constant observation of it but she had not seen him for eight years and had not used the drops for six years. There had been no pain nor inflammation in the left eye. Left vision was 20/40—, unimproved by refraction; the media were clear and the fundus normal with the exception of the disc which showed a wide and deep cup with marked pallor. The cor-

nea measured 12.5 mm. in diameter and the intraocular pressure was 52 mm. Hg. The peripheral field showed a marked upper nasal defect and the central field a large Bjerrum scotoma below.

On the following day a flap sclerotomy after the method of Cruise was done and the patient placed on dicumarol for 10 days. One month after operation the tension had been reduced to 17 mm. Hg. and has remained in that vicinity since. There was no improvement in the field a month after the surgical procedure, but on June 28th an improvement had begun. The peripheral field showed continued improvement on September 24, 1947, but the blindspot had not responded and consequently in early October she was again hospitalized for two weeks of dicumarol therapy. By November 7, 1947, the field and blindspot showed marked improvement and when last seen on January 13, 1948, no further changes were noted. The central vision has improved to 20/20—.

COMMENT

Until recently there has been no alarming increase in the prothrombin time of any patients undergoing treatment with dicumarol. However, there are two recent patients who have been taking the drug at home with weekly checks of the prothrombin time, after it was thought that their maintenance dosage had been adequately determined, and who have suddenly developed hematuria with all the symptoms of renal calculus.

Upon examination by a urologist, nothing of note was found except a marked increase in the prothrombin time. Because of the experience of these two patients, I feel that it probably will be safer in using the drug to have daily checks of the prothrombin time for some weeks rather than let the patient be checked weekly after a supposed stabilization of the blood level during a 1-week or 2-week period of frequent observation.

Of the 9 cases reported in this preliminary report, 6 had dicumarol with benefit some months or years after the tension had been reduced by surgery but, in spite of the reduction of tension, the field changes showed continued progression. One patient had dicumarol immediately following operation and five months later had a second course following which there was marked

improvement in the fields. The remaining 2 patients had dicumarol immediately following operation with improvement in the visual fields. Therefore, it is impossible to say whether dicumarol was the effective agent in the gain in field or that surgery played the important role. However, it has generally been assumed in the past that the field that was lost in glaucoma was not restorable by any means except in very rare instances.

There are many questions that come to mind in relation to this problem which I cannot answer at this time. This report is presented because it has seemed to offer some hope in what has formerly been an almost hopeless condition and, while the work that has been done is purely preliminary, it would seem to warrant further investigation by many more ophthalmologists.

HISTORICAL MINIATURE

Egyptian Ophthalmology

Concretion of the meibomian glands and white corneal scars were recognized by the Egyptians. For the latter they applied turtle brain in honey. Their use of the aqueous of pigs' eyes as a vehicle for drugs, the brain of the turtle and man, to say nothing of blood, milk, and dung points to a faith in organotherapy which has again been advocated in our time.

Hirschberg, *Graefe-Saemisch Handbuch.*

THERAPY OF SOME OCULAR INFLAMMATIONS BASED ON IMMUNOLOGIC PRINCIPLES*

F. HERBERT HAESSLER, M.D., AND HERMAN A. HEISE,† M.D.

Milwaukee, Wisconsin

It is our purpose to call attention to the great value of bacterial antigens in the treatment of some ocular inflammations. Its successful use depends on an understanding of a process that involves two factors: antigen and antibody. The remainder of this paper —after a few introductory remarks—will exhibit the process as simply as is consistent with adequate understanding and without violence to the truth. It will also elucidate the practical application of the principles.

Abundant clinical experience has convinced us that vaccine therapy is a great help in many situations and indispensable in some. We base our belief on our clinical experience with several dozen patients in whom resistant inflammations of the conjunctiva and of the iris were successfully treated. We will not describe this clinical material. It is too small for statistical analysis and the details of the observations on an individual patient could only illustrate a principle, not give proof of its validity. We have found it so useful in some inflammations that failed to respond to therapy with drugs or antibiotics that we want to communicate our faith in its efficacy.

The successful use of vaccine therapy depends on an understanding of immunologic principles which are not new, and which are accessible in the more comprehensive textbooks of bacteriology, such as that of Topley and Wilson.

Our purpose is to select the data which are essential to an understanding of vaccine therapy. The ophthalmologist need not have at his fingers' ends a grasp of the entire subject which constitutes the full-time occupation of the immunologist. He needs only a few principles which are easily outlined. We present such an outline which, to the immunologist, may seem oversimplified, but we believe that this outline is not only a safe guide in the treatment of patients but a true description of one of the important processes of resistance to infection.

It has the same relationship to the therapy of inflammations that a road map has to travel. The road map is not a drawing of the countryside, but a series of symbols that are easily understood and if properly applied lead the traveler to his destination without danger or detours. Similarly, our scheme is a simplified diagram which is a symbol for the essential reactions that take place in the resistance to infection. It is not only a safe guide to therapy but also to an understanding of fundamental processes in infection, tuberculin therapy, and allergy.

THE IMMUNOLOGIC PRINCIPLES

The fundamental mechanism of the tissue injury that results from the introduction of all organisms except the few that are primarily toxic—diphtheria, tetanus, gas bacillus, and botulinus—and also from the nonliving agents in allergic individuals, is the reaction between antigen and antibody. Most antigens are protein and in infections they are protein from the protoplasm of the invading organisms. The tissues of the host react to the invasion of antigen by the production of antibody. Antibody is doubtlessly not a single simple substance but all the reactions in which it is involved can be understood by conceiving of it as a single reacting unit. In this discussion it will be referred to as a substance.

Antigen alone is harmless to all tissues. As time goes on, antibodies develop in response to its presence. Antibodies alone are also harmless but when antigen reacts with
FIG. 1   FIG. 2

Fig. 1 (Haessler and Heise). Identification of symbols in the other figures: (a) Eye. (b) Circulation of fluids in tissues in and about the eye. (c) Antigen. (d) Blood stream. (e) Antibody. (f) Skin.

Fig. 2 (Haessler and Heise). Fundamental characteristics of antigen and antibody: (a) Antigen alone is harmless to a cell. (b) Antigen combined with antibody that is attached to a cell is destructive.

antibody that is attached to a tissue cell, the reaction is destructive. It is the immunity, not the antigen, that causes the trouble. Antigen increases because of multiplication of the invading organism. Antibody increases in response to the increased antigen. When enough of both substances is present to involve many cells in a tissue, clinical signs of inflammation become manifest.

The interval of time between the first introduction of antigen and visible signs of inflammation is the incubation period of the disease. It is the proliferation of antibody, not the supposed accumulation of enough antigen to injure tissue cells that marks the end of the incubation period. This was pointed out by von Pirquet years ago and still is not clear to everyone. Antibodies may be elaborated at a much greater rate than antigen. When they are, 1 or more of 3 events will take place:

1. The antibody destroys the antigen at the site of invasion.

2. The antibody enters the body fluids. Antigen-antibody reactions that take place here—humeral reactions—are harmless to the primarily inflamed tissue.

3. The antibody may become concentrated in a secondary focus in some other tissue. When it does, this tissue will become inflamed immediately if antigen is introduced into it. This is the probable process of focal infection.

The first 2 of these 3 reactions lead to healing at the original site of inflammation but leave the tissue "sensitive" to reintroduction of the same antigen. The word "immune" may be substituted for "sensitive" in this sentence. It is identical in meaning. In the course of time, however, the supply of antibodies gradually decreases and the tissue loses its sensitivity but, if a similar antigen should be introduced anew, the production of antibodies will proceed much more rapidly.

The essential processes of acute inflammation and spontaneous recovery have just been described. However, antibody is not always developed in adequate quantities to deplete the invaded tissue of antigen. It may develop just rapidly enough to keep the antigen in check, and yet not rapidly enough to wipe it out completely. In this event a long-continued smouldering inflammation results—the situation for which vaccine therapy is indicated.

Vaccine therapy is essentially the introduction of an antigen similar to the invading one into tissues of another organ—not the infected one. In practice, this other tissue is almost always the skin and the process has unfortunately been named "desensitization." Actually we are not desensitizing the skin but rather sensitizing or immunizing it. We are inducing it to become the site of origin of an adequate supply of antibody. When treating an eye, we strive to inject antigen into the skin in such quantity that local antigen-antibody reactions will take place in the skin and humeral antigen-antibody reactions which are harmless to the eye will deplete the eye of antigen. The essential point in understanding vaccine therapy is that we are not desensitizing any tissue; on the contrary, we are sensitizing another tissue—the skin. We are shifting the site of the harmful
Fig. 3 (Haessler and Heise). Infection, incubation period, and spontaneous recovery: (a) Antigen alone, derived from invading organism, produces no inflammation. Antibodies gradually develop. This is the incubation period. (b) Antigen and antibody react in tissues of eye and cause inflammation. (c) Antibodies have destroyed antigen. Eye has recovered.
Fig. 4 (Haessler and Heise). Treatment. (a) Eye is inflamed. Antigen-antibody reactions in eye. (b) Antigen is introduced into skin. (c) Skin elaborates antibodies. Excess antibodies enter blood stream. (d) Antigen enters circulating fluids from eye. Humeral reactions destroy antigen. Eye recovers. (e) Antibodies only in skin, blood stream, and eye. No inflammation. All tissues immune; that is, sensitive to further introduction of the same antigen. (f) Overdose of vaccine. Excess antigen enters blood stream and eye, where it reacts with antibody and produces inflammation.

antigen-antibody reaction from the eye to the much less vulnerable skin. The essence of the treatment is the shifting of the shock organ.

The danger of vaccine therapy is overdosage. If we give too large a dose, we introduce a quantity of antigen that is large enough to produce a harmless local reaction in the skin, a harmless humeral reaction, and to leave an excess of antigen that will reach the eye and produce a dangerous focal reaction there. A proper dose inadvertently injected into a vein produces the same deleterious effect as an overdose.

These reactions take place with all nontoxic antigenic substances, living or dead, of whatever source. The principles of treating allergic lesions are precisely similar.

DETAILS OF VACCINE THERAPY

The practical corollaries of the reactions are these: One must have a vaccine which contains the antigen which is the cause of the inflammation. In conjunctival inflammations a suspension of a 24-hour heat-killed culture of the invading organism is the surest and most convenient source of antigen. When the causative organism gives rise to a soluble antigen, the filtrate of a 4-day veal brain broth culture diluted to 1:10,000 is efficacious. In iritis a similar culture from the tissue of primary infection, for example, nose, throat, or prostate, is often available. If it is not, stock cultures of the common etiologic factors, usually streptococcus, pneumococcus, and staphylococcus, can be used. In probable tuberculous lesions a tuberculin or P.P.D. are readily available antigens.

The important factors to emphasize about dosage are size and interval. The dose must never be large enough to produce a focal reaction. We use extremely small doses with success. We start with the intracutaneous injection of 0.01 cc. of a suspension of organisms from a 24-hour culture (not over 10 million organisms) and gradually increase the dosage in succeeding injections until we note clinical improvement of the lesion. After that we no longer increase the dose. There is no theoretical reason for doing so and our practical experience encourages us to be guided by reasoning based on the theory we have outlined.

This is probably as true of tuberculin as of other antigens but we do not, as yet, have adequate clinical data on the basis of which we could affirm or deny this statement with confidence.

The interval between injections may be 3 to 5 days in the beginning of treatment when the dose is small. Later the interval may be increased but not to an extent that there is a falling off in the production of antibodies. The patient's observations are of use in determining this interval. Frequently we have been told by a patient who had been asked to return in 2 weeks that he felt well for 6 days and then gradually became vaguely uncomfortable.

The illustrations in the text represent crucial moments in the diagrammatic motion picture that accompanied the presentation of this essay.

SUMMARY

When the tissue of a host is invaded by antigen, it responds with the development of antibody. Neither the antigen nor the antibody is harmful to the tissue. The reaction of antigen with antibody that is attached to a tissue cell is destructive to the cell. If the number of antibodies exceeds the antigen, spontaneous healing takes place. When it does not, one strives in rational therapy to have this antigen-antibody reaction take place in the body fluids or in a less vulnerable organ, the skin. Injection of antigen into skin in minute quantities accomplishes this object without danger. An excessive injection is dangerous because the excess of antigen can reach the diseased organ and increase the inflammatory process.

SCLERAL STAPHYLOMA AND RETINAL DETACHMENT*

DERRICK VAIL, M.D.
Chicago, Illinois

In 1940, before this society, I reported a case of equatorial scleral staphyloma and retinal detachment successfully cured by excision of the staphyloma. In 1945, the second eye of this patient developed scleral staphyloma and retinal detachment. The staphyloma was excised and the retina became reattached. The latest report from this patient indicated that she had no further disturbance in either eye and the corrected vision has remained useful (20/30+ in the right eye, 20/40+ in the left).

Since then, in a recent series of 34 retinal detachment cases, 8 additional cases, all more or less similar, of scleral staphyloma and retinal detachment have been operated upon by me. The series is too small to draw any conclusions regarding the frequency of this finding, but is significant in indicating that the combination of staphyloma and detached retina is perhaps not infrequent.

So far as could be determined no other author, surprisingly enough, has reported this association. It is incredible, when one considers the enormous amount of time and work devoted in the past to studies of the pathogenesis and pathology of retinal separation, that this circumstance was not encountered and remarked. It is therefore entirely possible that somewhere in the vast literature on retinal detachment, a note of this combination and its significance is to be found.

PATHOGENESIS

The pathogenesis of scleral staphyloma has had little study and attention. Considered as a part of the terminal stage in absolute glaucoma or the result of obvious injury or inflammation of the sclera plus increased intraocular pressure, it has been lightly dismissed in our systems of ophthalmology and textbooks, except in that of Fuchs's. Mention is made of the three types, classified for many years as intercalary, ciliary, and equatorial staphylomas, depending on their location.

Birnbacher and Czermak, in 1886, were the first authors to discuss the evolution and progression of scleral staphyloma. According to Mattice, from whom I have freely borrowed, these authors assumed that a weakened spot in the sclera begins to yield before a normal or increased intraocular pressure. Since the sclera is relatively inelastic, the inner fibers cannot stretch sufficiently to preserve their integrity, and finally break off short, the broken ends retracting somewhat. Successive layers of scleral fibers are thus exposed to the disintegrating process and are broken through. The scleral wall becomes thinner and yields altogether to the force of the intraocular pressure, thus forming an ectasia.

The histologic findings of these authors revealed that the edges of the excavation on the inner surface of a large and old staphyloma are slanting and that it presents a roughened surface due to the irregularly broken ends of the scleral fibers. Only the deepest (that is most superficial) fibers that form the floor of the excavation are intact. These fibers, however, may later rupture until eventually the scleral wall is broken entirely through.

The relation which the uvea bears to such staphylomas was found to depend upon the degree of inflammation in the sclera and uvea. In cases where very little inflammation has occurred, the uvea retains its normal position and bridges across the mouth of the excavation. However, in cases with more extensive inflammatory changes and exudation, the uvea is found firmly attached to

Fig. 1 (Vail). Scleral staphyloma, showing the torn fibers of its inner third.

the sclera as a thin atrophic layer lining the walls and floor of the excavation.

If scar tissue has been found in the uvea prior to the beginning of the staphyloma, the uvea is found ruptured since stretching is impossible. A normal uvea, however, may also rupture if the mouth of the excavation becomes too wide. In most of their cases, Birnbacher and Czermak found the choroid adherent to the walls and floor of the excavation. As a result of their studies, these authors laid down two general rules which govern the formation of staphylomas:

1. Inflammatory changes can always be demonstrated in the sclera.

2. The staphyloma always develops at a point' of least resistance in the sclera, for example, where it is perforated by blood vessels.

Mattice, in 1913, described the histologic findings in a case of equatorial staphyloma that had no connection whatever with the point of entrance of blood vessels, nor with inflammatory changes that could be observed in either retina, choroid, or sclera. The choroid was not pressed against the floor of

the excavation but loosely filled out the space between the floor and the lamina vitrea, bridging over the mouth of the excavation, indicating that intraocular pressure alone was not responsible for the ectasia. The floor of the excavation was covered by a ciliary artery and nerve and Mattice thought that this relationship had a direct bearing on the origin of the excavation. He compared this finding to the gradual grooving of bone by arteries with age and considered that the continued action of blood pressure within the walls of the ciliary artery, particularly if sclerotic or calcified, would form a groove in the sclera, especially if the latter were weakened by disease or injury.

Fuchs mentioned the diminished resistance of the sclera as an infrequent cause of ectasia of the sclera even in the presence of normal intraocular pressure. It is found in cases of deep scleritis, tumors (malignant neoplasms, gummatous or tuberculous nodules), and injuries, especially ruptures of the sclera. He said, "Scleral ectasiae arising in this way lead subsequently to elevation of the intraocular pressure, which then, however, must be regarded not as the cause, but as the result of ectasiae, even though, just as in the case of ectasiae of the cornea, it does contribute to make the latter larger still."

A study of two specimens of scleral staphyloma found in the pathologic laboratory of the Eye Department, Northwestern University, brings out several very interesting points in support of the work of Birnbacher and Czermak.

Figure 1 is an illustration of a section of an eye removed from a patient, aged 77 years, for a suspicious intraocular tumor and secondary glaucoma. The histologic diagnosis in addition to the staphyloma was an occlusion of the central vein. A staphyloma the size of a globe, with smooth surface, was found beneath the internal rectus muscle, measuring 25 by 21.5 by 22 mm.

There is marked thinning of the nasal sclera from the ora serrata backward to

well beyond the equator. Just in front of the equator there is a circumscribed scleral staphyloma within which the inner third of the scleral fibers are torn, while the outer two thirds bulge sharply outward. Between the frayed ends of the torn fibers, filling the staphyloma, there is a loose areolar tissue which contains a few round cells and many fibroblasts. The choroid and retina in this and the immediately adjoining region are reduced to a thin, partly fibrous, partly glial membrane, which does not follow the outline of the staphyloma but crosses or bridges it. Anterior to this region the retina shows excessive cystoid degeneration. The nasal sclera in general shows poor stain of its nuclei. Several small, thin-walled vessels course through the staphylomatous portion of the sclera. There is marked retinal and choroidal vascular sclerosis throughout.

The second specimen is that from a patient, aged 75 years, (fig. 2). No history is obtainable. The histologic diagnosis is secondary glaucoma. The globe measures 30 by 24 by 24 mm. (high myopia). There is a circumscribed staphyloma in the diffusely

Fig. 3 (Vail). Adjacent to the staphyloma which shows a cystic degeneration of the retina with bands of glial fibrous strands across the cyst.

thinning sclera of the posterior polar region. The inner two thirds of the scleral fibers are torn, leaving frayed edges, the outer third bulges in an ampulliform fashion. Its inner surface is lined by extremely atrophic choroid and the thin outer wall of a large retinal cyst. There is a detachment of the posterior vitreous. The subhyaloid region and the retinal cysts are filled with the same pink coagulum. Anterior to the staphyloma is to be found an enormous area of cystic degeneration of the retina. The outer wall has prolapsed into the scleral staphyloma.

These two specimens are, I believe pertinent to the discussion since they reveal the method of the development of the staphyloma of the sclera supporting the previous histologic studies of this condition by other authors and also indicate that even in the presence of increased intraocular pressure, the retina may bridge over the staphylomatous area. In addition, Figure 3 reveals the mechanics of the development of a retinal

Fig. 2 (Vail). Scleral staphyloma, showing ruptured scleral fibers and containing a retinal cyst.

tear as a result of contraction of glial fibrous bands in a retinal cyst.

We see, therefore, that a staphyloma of the sclera can arise in different ways. Scleritis and episcleritis are not unusual ocular diseases. Other factors besides inflammation of the sclera may play a role in weakening its inner wall, factors such as choroiditis, cyclitis, endarteritis, phlebitis, or perhaps some nutritional condition of the sclera comparable to scleromalacia or senile hyaline scleral plaques.

It is easy to conceive of the development of a tear in the inelastic retina bridging over a diseased area in the sclera that is stretching and yielding to intraocular pressure. This is particularly likely when one considers that the retina in this area is probably diseased and cystic as is seen histologically. Such a tear was found in almost all of the cases about to be described.

CASE REPORTS

Case 1. A woman, aged 57 years, had a large balloon detachment of the retina in the upper temporal portion of the left eye. No tear was observed. The ocular tension was subnormal; transillumination was negative for shadow. On exposure of the scleral operative field, a scleral staphyloma occupying the area between the tendons of the superior and external rectus muscles was found. It measured 12 by 16 mm. and began abruptly at a point 6 or 7 mm. from the limbus. The staphyloma was excised more or less according to Müller's technique. A cure of the retinal detachment resulted and the patient has retained useful vision in the left eye since then. (Case reported in 1940.)

Case 2. The same patient described in Case 1. In 1945, she developed a similar detachment in the upper temporal portion of the right eye. No tear was seen and the ocular tension was subnormal. A staphyloma of the sclera in the area of the detachment was observed. On exposure it was found to arise abruptly about 10 mm. from the limbus and measured approximately 20 by 7 mm., between the 8- and 10-o'clock positions. This was excised in a fashion similar to the operation done on her left eye. A cure of the detachment resulted and the vision in this eye has likewise remained good to date. (Case reported in 1946.) The refraction changed as the result of the operation from, R.E., —0.5D. sph. ⊃ —0.75D. cyl. ax. 175° to +1.25D. sph. ⊃ +4.5D. cyl. ax. 175°; L.E., from —1.0D. sph. ⊃ +1.75D. cyl. ax. 115° to +3.5D. sph. ⊃ +3.25D. cyl. ax. 25°.

Case 3. A man, aged 60 years, was examined on November 11, 1946. Four weeks before he noticed a veil descending over the vision of the left eye. A large dark balloon detachment of the retina was found in the upper temporal portion. A very large horseshoe-shaped tear was observed 18 mm. from the limbus at the 1-o'clock position. Ocular tension was subnormal (14 mm. Hg, Schiøtz). Transillumination was negative.

At operation on November 23, 1946, an irregularly shaped staphyloma of the sclera was found. It measured 8 by 10 mm. and arose abruptly 10 mm. from the limbus. There was some question for a moment if this could be a melanoma of the choroid. However, light shone through it readily and the sclera was obviously thinned and dented easily on palpation with the tip of a muscle hook. Instead of excision, a series of ignipunctures in and around the area was performed and some yellowish subretinal fluid was evacuated. On the tenth postoperative day a massive vitreous hemorrhage occurred which began to clear shortly before his discharge from the hospital on December 14, 1946.

On his return three weeks later, the retina at the site of the operation was found to be in place and showed the usual postoperative pigment action. However, in the floor the retina was detached in a trilobular fashion. On February 1, 1947, the involved area was operated on with diathermy coagulation, without a completely successful reapposition of the retina. Final vision on May 21, 1947, was counting fingers at 10 feet. Tension was 22 mm. Hg (Schiøtz).

Case 4. A woman, aged 59 years, was examined on March 12, 1947. Five days before she had noticed blurred vision in the left eye. An extensive detachment of the retina in the temporal area of the left eye from the 2- to 7-o'clock positions was seen. The retina was in folds with the area of greatest detachment at the 4-o'clock position. No tears were seen and transillumination was negative for shadows. The ocular tension was subnormal.

At operation, a staphyloma of the sclera arising 9 mm. from the limbus and measuring 8 by 6 mm. at the 3-o'clock position was seen. It was excised according to the modified Müller technique. Nonperforating ignipunctures were made on each side of the scleral excision. The result was a failure. The retina remained detached from the 4- to 8-o'clock positions.

Case 5. A man, aged 46 years, was examined on April 2, 1947. He had a detachment of the retina in the right eye of two weeks' duration. A balloon, dark detachment was seen beginning at the 10-o'clock position and extending to 3 o'clock. There was a large horseshoe-shaped tear at the 12-o'clock position and 16 mm. from the limbus. Another fishhook vertical tear, not connecting with the first one, at the 1-o'clock position, extended to 18 mm. from the limbus. The ocular tension was low, 10 mm. Hg (Schiøtz).

At operation, a large staphyloma of the sclera extending from the 10- to 1-o'clock positions, arising 10 mm. from the limbus and extending to the equator, was found. The area was extensively treated

with diathermy ignipunctures, most of which were perforating, and particularly heavy in the area of all tears. The sclera shriveled under the treatment. At the first dressing, 48 hours later, the interior of the eye was found filled with blood and there was a severe ocular reaction. The blood gradually absorbed, but traces of it were still present three months later, and the posterior surface of the lens above was blood-stained. This has persisted.

The retina was reattached and the field of vision became full. Ocular tension on September 27, 1947, was 16 mm. Hg (Schiøtz). Preoperative refraction was: −0.5D. sph. ⊃ −2.5D. cyl. ax. 90° (vision, 20/20. Postoperative refraction on September 27, 1947, was: −0.5D. sph. ⊃ 3.0D. cyl. ax. 110° (vision, 20/30.)

As a result of, the extensive diathermy of the sclera beneath the superior rectus tendon, severe scarring resulted and there remained 25 degrees exotropia and 14 degrees right hypertopia in the primary position, necessitating later freeing of the adhesions and recession of the external and superior rectus tendons with considerable improvement, but still marked limitation of movement downward and outward. An annoying diplopia is therefore still present, although the patient is learning to suppress the vision in the right eye.

Case 6. A man, aged 22 years, was examined on April 18, 1947. The upper temple part of the retina in the left eye had become detached in 1941 and was operated upon successfully with diathermy coagulation. No staphyloma of the sclera in that eye was noted. In October, 1946, the patient noticed blurring of vision in his right eye. Examination on April 18, 1947, showed what was considered to be a large cystic detachment of the retina involving the temporal zone from the 5- to 11-o'clock positions with multiple small tears in a disinsertion zone at 9 o'clock particularly. Tension was 15 mm. Hg (Schiøtz).

At operation on April 21, 1947, a bluish rectangular staphyloma of the sclera was observed beneath the tendon of the lateral rectus muscle and extending about equally above and below the edges of the tendon. It measured 12 by 20 mm. and began about 8 mm. from the limbus. A scleral resection of the staphyloma, 10 by 16 mm., was performed and the area around the wound was treated with perforating ignipunctures. The retina did not become reattached and the result was a failure. Postoperative tension was 12 mm. Hg (Schiøtz).

Case 7. A woman, aged 43 years, was examined on April 18, 1947. The left eye had had a retinal detachment seven years before and was operated on elsewhere with failure. A funnel-shaped detachment was now present. About March 15, 1947, she noticed blurred vision in the right eye. A large balloon detachment of the retina was found in the temporal portion of the right eye, extending from the 7- to 11-o'clock positions. It was of dark color and encroached onto the macular area. At the 8-o'clock position could be seen a series of small round holes in the cystic (shagreen) retina, 16 to 18 mm. from the limbus. Tension was 12 mm. Hg (Schiøtz).

At operation a bluish discoloration was noticed beneath the tendon of the lateral rectus. It measured 12 by 12 mm. and was roughly triangular in shape. It dented easily on pressure and transillumination of the area revealed a thin sclera. A 12 by 8 mm. strip of sclera was excised. The underlying choroid was present and not adherent to the sclera. It was obviously atrophic. A small amount of vitreous was lost. The lips of the wound were treated with diathermy coagulation (nonperforating) after the sutures were tied. A successful result ensued. Preoperative refraction was: −1.5D. sph. ⊃ 1.0D. cyl. ax. 35° (vision, 20/100). Postoperative refraction was: −1.5D. cyl. ax. 60° (vision, 20/40+).

Case 8. A man, aged 76 years, was examined on December 12, 1947. His right eye had been lost as the result of an accident at the age of 21 years. An extracapsular cataract extraction was done in the left eye on July 27, 1946, followed at intervals by two needlings and a capsulotomy (October 26, 1947). On November 11, 1947, his vision became blurred and a detachment of the retina developed in the temple side of the eye.

At operation a staphyloma of the sclera was observed. It resembled a leaf, the inferior portion lying largely under the lateral rectus muscle, measuring 9 by 8 mm., and a superior portion extending vertically and laterally, measuring 4 by 6 mm. There was a connecting isthmus between the two leaves. A piece of sclera from the 2- to 4-o'clock positions, 5 mm. wide and 12 mm. from the limbus, running through as much of the staphyloma as possible, was excised. No diathermy was used. A considerable amount of fluid vitreous escaped, and the eye became very soft. Failure resulted.

Case 9. A woman, aged 62 years, was examined on January 30, 1948. Two months before she had noticed sudden partial loss of vision in the left eye, and three days after onset she awakened to find the sight in the left eye "gone." Examination on January 30, 1948, revealed an extensive detachment of the lateral part of the retina of the left eye from the 11- to 5-o'clock positions, with the area of greatest elevation at 2 o'clock. Here could be seen a large horseshoe-shaped tear 18 mm. from the limbus. The retina was dark in color. Tension was 10 mm. Hg (Schiøtz) and transillumination was negative for shadows. There was an incipient cataract present in each eye.

At operation a staphyloma of the sclera was discovered. It was situated between the tendons of the superior and lateral rectus muscles. It consisted of three radial bluish pigmented areas about 1 to 2 mm. wide, each one beginning at 8 mm. from the limbus. The entire area involved was approximately 8 mm. wide and extended just beneath the upper edge of the lateral rectus tendon.

An elliptical area, 14 by 5 mm., of the sclera, 8 mm. concentric to the limbus, was outlined with a knife. Four double-armed (cutting-edge needles) 4-0 black silk sutures were placed in mattress fashion from sound sclera to sound sclera and tightly tied. There resulted a tuck of the staphyloma. Loss of subretinal fluid occurred around the

sutures, softening the eyeball, and thus increasing the ease of tying them. The tucked portion of the staphyloma was excised, and several gaps were closed with single black silk sutures. About 25 diathermy punctures were placed around the wound. Healing was uneventful in spite of the difficulty of keeping this patient quiet.

Preoperative refraction was: +1.0D. sph. ⊃ —2.0D. cyl. ax. 45° (vision, light perception). Postoperative refraction (April 1, 1948) was: +0.5D. sph. ⊃ +1.75D. cyl. ax. 120° (vision, 20/50). The postoperative field was full; there were some vitreous opacities and the tension was 16 mm. Hg (Schiøtz).

Case 10. A man, aged 59 years, was examined on February 10, 1948. One week before, the vision in his left eye suddenly blurred. Examination of the left eye showed some lens spicules, a few floating opacities and a large balloon-shaped retinal detachment extending from the 11- to 5-o'clock positions as far as the optic nervehead. The outline was sharply defined. There was a large horseshoe-shaped tear at the 2-o'clock position, 16 mm. from the limbus and a second round tear at 3 o'clock, 19 mm. from the limbus. The color of the detachment was dark. Transillumination revealed no shadow. The ocular tension was 14 mm. Hg (Schiøtz).

At operation (February 18, 1948) a staphyloma of the sclera was found extending from the 12- to 5-o'clock positions. The posterior border was 18 mm. from the limbus and the staphyloma measured 11 mm. by 30 mm. It arose about 7 mm. from the limbus. There were radial lines and areas in the staphyloma, reflecting the bluish color of the choroid. It was darkest at the 2-o'clock position and lightest at 10 o'clock.

Four mattress sutures of 4-0 silk were inserted in the staphyloma from 12 to 17 mm. from the limbus from 1 to 4 o'clock. A tucking of the sclera was therefore made and a piece of sclera, roughly 5 by 11 mm., was excised. The closure of the wound was further secured by placing of several single-armed silk sutures in gaping areas. A large amount of fluid vitreous, and a bead of solid vitreous was lost.

A row of perforating ignipunctures was made with the diathermy, 12 and 18 mm. from the limbus from the 12- to 5-o'clock positions. Another series of nonperforating diathermy punctures was made on either side of the scleral wound. The conjunctiva was closed with continuous black silk sutures. Inspection of the retina at the close of the operation revealed many folds in the area of the resection. The media was clear.

There was considerable postoperative reaction, as manifested by edema and chemosis of the lids and bulbar conjunctiva. For three weeks there was no red reflex obtainable; the retina in places could be seen with oblique illumination. Although the patient had good light perception, the prognosis was considered hopeless. At the end of three weeks the edema and chemosis had cleared and a red reflex became apparent, first on the nasal and later on the temple side.

On April 22, 1948 (two months after the opera-

tion), the ocular congestion was clearing. The peripheral field of vision was full except for a small notch up and out. There was a small central scotoma. The red reflex was bright. A large scar of the retina, with pigmented edge, occupied the temple portion of the eyeball, with some blood-staining of the retina in the floor extending into the macular area. The tension was 12 mm. Hg (Schiøtz).

Preoperative refraction was: +1.5D. cyl. ax. 75° (fingers at 10 feet). The postoperative refraction two months later was: —1.0D. sph. ⊃ +4.5D. cyl. ax. 180° (20/100+).

COMMENT

Two of the described cases were treated with diathermy alone. One was a failure. The successful one, however, had had so much coagulation, some of it involving the ciliary zone, that a severe intraocular hemorrhage and cyclitis resulted, leading to a long convalescence and resultant and perhaps permanent blood-staining of the posterior surface of the lens and vitreous. In addition, so much scar tissue bound down the superior rectus muscle, and to some extent the external rectus muscle, that a marked muscle imbalance occurred, requiring further surgery in an effort to overcome a very annoying diplopia.

The rest of the patients were operated upon by scleral resection combined with some diathermy coagulation. The last two patients were treated surgically by mattress sutures passed through the staphyloma which, on being tied, resulted in a tuck of the sclera that was then excised without too much difficulty. This idea was obtained from Gayer Morgan who, in 1943, successfully excised a ciliary staphyloma in this fashion. It is apparently safer and easier to perform than is the more tedious excision hitherto described by Müller, Lindner, Pischel, and myself.

The placing of a row of perforating ignipunctures near to the wound further enhances the chances of success and the avoidance of hemorrhage. Of the 8 cases of scleral resection, 4 were total failures; 3 can be considered successful and 1 a partial success. The operations were all performed under sodium pentothal intravenous anesthesia, and the usual method of exposure of the field of operation was performed.

CONCLUSIONS

This small series of cases permits one to draw the following conclusions:

1. Retinal detachment may occur subsequent to a scleral staphyloma in the affected area.

2. In most of the cases the detachment was dark and ballooned. There was usually to be found a large horseshoe-shaped tear in the area of greatest detachment.

3. Most of the staphylomas occurred in the lateral portion of the eyeball.

4. Unless the staphyloma is small, diathermy alone offers the least chance of successful surgery.

5. Excision of the staphyloma, after first tucking the affected sclera, appears to be relatively simple to perform. Diathermy ignipunctures can be placed around the scleral wound, thus increasing the chance of success and reducing the hazard of intraocular hemorrhage.

6. Scleral staphyloma and retinal detachment occur perhaps more frequently than has hitherto been realized, and the presence of a staphyloma is more common than suspected.

7. The diagnosis is made by the bluish, bulging appearance of the affected sclera, the easy indentation of its surface, and its increased transparency on transillumination.

THE USE OF PROCAINE INTRAVENOUSLY IN OPHTHALMOLOGY*

A PRELIMINARY REPORT

ISADORE GIVNER, M.D., AND DAVID J. GRAUBARD, M.D.
New York

The recent introduction of intravenous procaine infusion in the management of pain in trauma and inflammatory conditions, as well as in the pruritus of jaundice, the treatment of burns, as a substitute for morphine in postoperative care, and for serum sickness, has suggested the need for an investigation as to its possible value in ocular disorders.

In reviewing the literature on the use of

intravenous novocaine in ocular disorders, the following are worth recording:

Lutton, Roumer, Giroud, and Ferron were able to combat eclamptic amaurosis by the intravenous administration of recorcoin. Esente[1] used it in painful glaucomas where the results mostly were satisfactory (no statistics). Pain was relieved and intraocular pressure was reduced for much longer than the time during which the drug was administered. He noted that the simultaneous use of miotics may enhance these effects. The doses

given varied between 10 and 100 centigrams.

Mme. S. Schiff-Wertheimer and Mlle. Gaillard[2] used intravenous novocaine (1:100) in the treatment of thrombosis of the retinal veins. Uncertain results were had in central retinal-vein occlusion but satisfactory results were had in branch obstructions if they were treated early enough.

Lorofi[3] used intravenous novocaine in the treatment of visual difficulties caused by arsenical trypanocides. He had only 2 failures, with 7 successes and 2 ameliorations. When blindness was complete, 3 cases were successful and 2 were improved of the 7 cases observed.

Rouher[4] used intravenous novocaine in the treatment of retinal edema and found quicker absorption and lessening of visual disturbances that could be attributed to the injections.

CHEMISTRY

Procaine is para-aminobenzoldiethylaminoethanol, soluble in one part of water in which its reaction is neutral. It is stable and does not decompose at temperatures as high as 100°C. When injected intravenously in sublethal doses, two processes are initiated: (1) Hydrolyzation of procaine by an enzyme into para-aminobenzoic acid (PABA) and diethylaminoethanol (DEA); (2) acetylation of para-aminobenzoic acid.

Nearly 95 percent of the injected procaine can be found in the urine either as PABA, para-aminohippuric acid, para-aminobenzylglycuronate and DEA, or even as traces of procaine. Procaine or one of its hydrolytic products, PABA, has been shown to be removed from the blood stream in 20 minutes. It is thought that, in inflamed areas, procaine administered by the intravenous route has a two-fold action: (1) Direct action in the irritated nerve fibers; (2) indirect action of DEA on the endothelium of blood vessels. The basic structural similarity between DEA, benadryl, and choline must be noted. The mode of action, as with benadryl at the capillary bed, may be considered as a competition between histamine and DEA for a

given site of action or receptive substance; or the action might be explained from the clinical observations on a cholinergic type response—*DEA* has an *anticholinesterase* action.

STRUCTURAL RELATIONSHIP OF DEA-BENADRYL AND CHOLINE

PHYSIOLOGIC ACTION

In order to simplify the giving of the procaine, "procaine unit" was devised which is the amount of procaine calculated at 4 mg. per kg. body weight to be given in 20 minutes in a 0.1-percent isotonic saline solution. One gm. of vitamin C is added to 1,000 cc. of isotonic saline solution containing 1 gm. of procaine hydrochloride.

During the administration—after about 5 minutes the patient usually describes a sensation of warmth over the entire body—a dryness of the mouth may be experienced.

In order to see what changes occurred in the normal eyes during and after its administration, 12 cases were studied as tabulated in Table 1. Although tearing of the eyes and dilation of the pupils has been reported with larger and more concentrated doses, neither reaction was observed in this series.

The pupils remained the same size and

continued to react normally consensually and to light and accommodation. There was no change in the size of the retinal vessels or other evidences of caliber variation. The tension showed no appreciable fluctuation, either during the administration or 30 minutes after.

From its physiologic action and chemical nature, on theoretical grounds, it seemed that in conditions in which vasodilation would be of value, procaine intravenously might be of ocular aid (figs. 1, 2, and 3). Accordingly, several cases of occluded retinal vessels were studied including one case of Buerger's disease with an occlusion of a superotemporal artery. No change was noted after treatment that could in any way be interpreted as related to the treatment. In like fashion, no improvement that could be attributed to the medication was noted in the treatment of five cases of branch thrombosis. Several cases of diabetic retinopathy were likewise treated with no effect whatsoever.

USE IN GLAUCOMA

In view of the anticholinesterase action of procaine, a reduction of intraocular pressure in some forms of glaucoma might theoretically be expected. Accordingly, 10

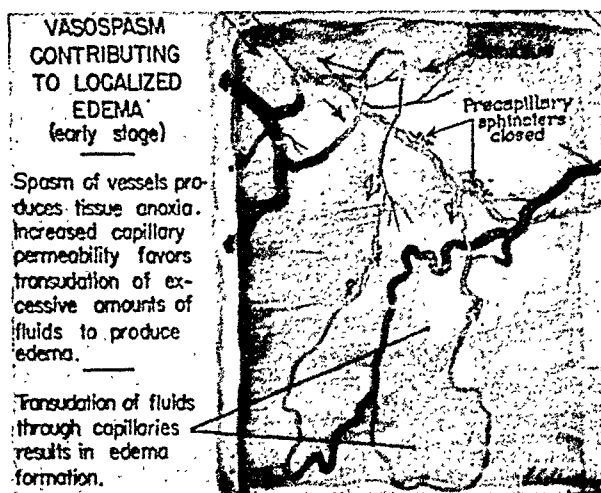

Fig. 2 (Givner and Graubard). Formation of edema.
Fig. 3 (Givner and Graubard). Mode of action of procaine.

cases of glaucoma (table 2) were investigated. Realizing that the drop in tension might not be noticeable until more than 30 minutes had elapsed, tensions were taken at 30-minute intervals for 2 hours after the administration of the procaine.

One might thus conclude that to date there seems to be no indication for the use of procaine intravenously in the treatment of glaucoma. Two cases of painful absolute glaucoma are, however, worthy of note. In these cases, there was marked relief of pain after intravenous procaine.

Case 1. H. S., a woman, aged 75 years, was a diabetic who had absolute glaucoma of the left eye. Vision was light perception and the unbearable pain could be controlled only little by the use of opiates. A cycloelectrolysis was done, as well as a retrobulbar alcohol injection, but the pain continued. After several weeks, enucleation was decided on but intravenous procaine was attempted as the last palliative. Pain was promptly controlled and, after three injections, no further injections were needed even though the tension remained high and no visible difference was seen by the examiner.

Case 2. N. Mc., a woman, aged 63 years, had a thrombosis of the central retinal vein of the right eye (incomplete) with secondary glaucoma. An iridencleisis had been performed, and the pain and tension were temporarily reduced. After sulfonamides were administered systemically for an infection not related to the operation, the tension rose again, hemorrhage appeared in the anterior chamber, and pain recurred and could not be controlled. The patient was given an intravenous procaine injection and experienced complete relief of pain. One other injection was given three days later, as a prophylactic measure against the recurrence of pain. The pain has not recurred (8 months). The patient had been using miotics previous to the onset of the pain and has used them subsequently. Following procaine administration, the tension was lowered to normal with miotics and has remained this way.

In one other condition, herpes zoster ophthalmicus, there was relief of pain after

the administration of procaine intravenously (2 cases). The injection had to be repeated, since the beneficial effect was only temporary (lasting two days after one injection). However, this type of therapy can be safely added to our armamentarium in the handling of the pain in this condition.

SUMMARY

1. Administration of procaine intravenously has no effect on the intraocular pressure either in normal individuals or in patients with chronic glaucoma.

2. No beneficial effect followed the use of procaine intravenously in occlusion of retinal arteries, in diabetic retinopathy, or in five cases of thrombosis of retinal vein branches.

3. Some relief of pain followed the administration of procaine intravenously in the treatment of herpes zoster ophthalmicus. The relief was not permanent.

4. Marked continued relief of pain was experienced in one case of absolute glaucoma and one case of hemorrhagic glaucoma.

5. Further studies will be made to see if there are other indications for its use in ophthalmology.

LOCAL USE OF ANTISTINE IN NODULAR EPISCLERITIS*

Erwin E. Grossmann, M.D., and Milton J. Loring, M.D.

Milwaukee, Wisconsin

According to Duke-Elder,[1] "Nodular episcleritis is a disease of obscure origin, of recurring but benign habit, characterized by the appearance of a localized nodular inflammatory focus in the episcleral tissues. The nodule seems to appear suddenly, and is always surrounded by an area of hyperemia and vascular dilatation. The entire globe may show some generalized hyperemia, but it is never as marked as the region about the nodule."

ETIOLOGY

The etiology has never been satisfactorily explained, but the texts and the literature of the present and past persist in incriminating the famous triad—rheumatism, gout, and focal infection. On this basis the treatment has been directed to the alleviation of pain in which the use of salicylates has been the most popular.

The condition called episcleritis periodica fugax has undoubtedly been frequently confused with the nodular type. Here, too, Fuchs,[2] father of its name, listed rheumatism, gout, and so forth as the etiologic agents. Although a great similarity may exist, the clinical differentiation between the two conditions is characterized by the transient character of the latter and its marked tendency to recur with great regularity.

It is noteworthy that, in this periodic type, the role of allergy has long been suspected. The most prominent view implicates hypersensitivity to the tuberculoprotein. Cases have been reported that appear strongly suggestive of allergy, although their authors did not always bring this out too clearly.

Balyeat[3] reported a single case in 1932 occurring in a physician, who was "apparently" cured by avoidance of certain foods. These authors quote the work of Edward Jackson, who after a period of several years of study felt strongly concerning the possibility of allergy as the etiologic factor.

Shoemaker[4] reported two cases of episcleritis caused by the excessive use of carbohydrates. However, instead of suspecting allergy, the author concluded that the condition was caused by poisons formed in the gastrointestinal tract, due to faulty digestion and carbohydrate metabolism.

Sinskey[5] and his co-workers also reported a case of episcleritis due to faulty carbohydrate metabolism, and they concluded that dietetic factors should be considered in each case.

In the recent literature Shepherd[6] reports five cases of episcleritis wherein the pain was relieved by the local instillation of histamine diphosphate. No attempt at etiologic correlation was made.

USE OF ANTISTINE

Because of the gratifying results obtained with the use of Antistine (Ciba) locally in a large series of known allergic eye disorders, it was deemed worthwhile to examine the effects of this drug.* The chemical known as Antistine hydrochloride† is the trade name for phenazoline hydrochloride, which is a synthetic preparation. It is made up in ophthalmic solution to a 0.5-percent concentration bearing a pH of 6.94.

Antistine was apparently first used internally at the University of Basel, and was found to be a useful antihistaminic in the

---

treatment of allergic diseases by Schindler[7] and Brack.[8] The ophthalmic solution was apparently first used by Bourquin,[9] who reported its use in 37 cases, many of which were nonallergic. As far as is known there is no specific report concerning its use in the treatment of nodular episcleritis.

IN EPISCLERITIS

A total of 22 patients whose conditions were diagnosed as episcleritis were treated by topical instillations of Antistine. In each case the clinical picture was characterized by a sudden onset of deep injection of a quadrant or more of the globe and with well-marked pain. There was a definite, elevated yellowish or grayish yellow nodule surrounded by intense redness and hyperemic blood vessels.

In the series of cases treated, only 3 patients admitted to having had a previous attack, 2 cases of which were in the opposite eye and were treated by this method; the other 19 patients were positive in their assertions that the present episode was the initial one. Two of these 3 are known tubercular patients.

Patients were instructed to instill the solution into the affected eye by eye dropper every three hours, and were told to return daily for further observation.

RESULTS

Of the total treated, 17 were men and 5 were women. The ages varied from 20 to 57 years. The apparent disproportion in sex distribution is accounted for by the unusually high proportions of men patients seen at this institution.

TABLE 1

SUBJECTIVE RELIEF OBTAINED WITH ANTISTINE THERAPY IN NODULAR EPISCLERITIS

Symptomatic Relief (Time)	Number of Patients
24 hours	3
24–72 hours	11
3 to 7 days	7
No relief	1

Noticeable relief in symptoms were obtained in all patients except one, as shown in Table 1. The patients were thoroughly questioned concerning this subjective relief, and there seemed no doubt that the element of pain had disappeared. Clinically the cure was noticeably less dramatic; yet the redness and the nodular elevation subsided within a few days after symptomatic relief (table 2).

Of the 22 cases, 7 were diagnosed as

TABLE 2

OBJECTIVE IMPROVEMENT OBTAINED WITH ANTISTINE THERAPY IN NODULAR EPISCLERITIS

Objective Improvement	Number of Patients
1 to 3 days	8
3 to 5 days	4
5 to 7 days	7
7 or more days	2
No improvement	1

pulmonary tuberculosis (the one failure occurred in this group), 1 had an associated rosacea keratitis, 1 had an undiagnosed skin disease, and 13 had no associated disease.

CONCLUSIONS

The use of the antihistaminic known as Antistine has shown to be highly efficacious in the treatment of nodular episcleritis. Of a total of 22 cases, 14 obtained dramatic relief from pain within 3 days, and 21 of the 22 were relieved in 7 days. Objective improvement was noted to be somewhat slower, the greatest improvement occurring in from 5 to 7 days after treatment.

The use of the antihistaminic was suggested by the inferences in the past literature concerning the possibly allergic etiologic factor in nodular episcleritis.

The local use of the drug was deemed to be the best method of application in view of the work by Friedlaender and Feinberg[10] suggesting that failure of relief when antihistaminics were used was due to insufficient drug reaching the site of action.

CIRCINATE DEGENERATION OF THE RETINA*

WITH REPORT OF A CASE

R. H. HENDERSON, M.D.
Wilmette, Illinois

Circinate degeneration of the retina is the term preferred by Duke-Elder for the disease originally described by Hutchinson, in 1876, as retinitis circinata. It was thoroughly reviewed by Edgerton in 1936 and another case reported by him.[1]

Since Edgerton's review, reports on seven more cases can be found in the literature. J. Margenot,[2] in 1936, reviewed the pathogenesis in two cases. M. Handmann,[3] in 1937, reported a case in a woman, aged 49 years, which he had observed for five years, from its incipient stage until the development of the white, degenerated area.

Two cases reported by Jules François[4] showed a retinal degeneration which began following thrombosis of the macular veins. The thrombosis preceded by several months the development of the retinal degeneration.

Holden[5] presented the case of a woman, aged 58 years, who had diabetes and high blood pressure. There were both old and new hemorrhages in the involved areas of the retina. S. Holm,[6] in 1941, reported the case of a woman, aged 82 years, in whom the eye was enucleated, but the suspected neoplasm was not found. In this case, the principal microscopic changes found were: increase in pigmented cells, some in massed formation and others scattered throughout the degenerating tissue; changes in the arrangement of rods and cones in some places, and, in others, the entire loss of rods and cones; round-cell infiltration of the retinal vessels.

Rebelo,[7] in 1943, reported a case in which there were discreet hemorrhagic areas within the ring of degenerating retinal tissue. His observation of normal appearing retinal vessels coursing uninterruptedly over the white areas of degeneration is in accord with the observation of most authors on this point.

One case in a child has been reported since Edgerton's review in 1936. This was reported by Morgan in 1944.[8] This case was in a boy, aged 8 years, in whom the chief complaint was reading difficulty. He had vision of 6/18 in the right eye and 6/5 in the left. There was a history of concussion at seven years of age with bruises over right side of head, so that the right eye was closed. No definite etiology could be established in this case and the concussion could only be referred to as a possible cause.

CASE REPORT

History. The case to be reported here occurred in a man, aged 57 years. He came to me first in May, 1947, on account of an acute blepharitis and conjunctivitis. He also complained of poor vision in his right eye. He had had his eyes tested for glasses one year previously but no mention was made by the examiner of any visual defect.

Vision was: R.E., counts fingers at 15 inches; L.E., 6/6—3. He gave a history of some prostatic involvement, but his general physical examination was otherwise essentially normal. Blood pressure was 165/85 mm. Hg, with urine negative for albumin and sugar, and Kahn test negative.

External eye examination. Mild, acute blepharitis of both eyes and a small chalazion in the left upper lid were present. There was acute conjunctivitis of both eyes. The pupils were regular, 3 mm. in diameter, and reacted normally to light and accommodation. The corneas were clear. Tension was normal in both eyes.

The ophthalmoscopic examination of the right eye was as follows: The cornea, lens, and vitreous were clear. The optic disc was sharply outlined and of normal appearance. There was marked tortuosity of some of the smaller veins and along the superior temporal vein were tortuous, dilated small veins, resembling clusters of grapes and occasionally punctate hemorrhages from these clusters. The retinal tissue immediately surrounding the macula was cloudy, with several punctate hemorrhages in the macular area. The macula was girdled by two semicircular arcs with open spaces at the nasal and upper temporal ends. The lower arc was wider in its middle portion, approximately 1½ times the diameter of the optic disc, and tapering somewhat toward both ends. This lower arc was yellowish white in color throughout its entire extent and had numerous small, rounded, discreet spots of a silvery sheen scattered over its surface. Its borders were irregular in outline, as though numerous smaller white spots had coalesced.

In the upper arc, the temporal half was yellowish white in color, but more narrow than the lower arc. The nasal half was a mottled slate gray in color and composed of numerous rounded, discreet patches which had not yet coalesced and were evidently of more recent origin. Coursing over this entire degenerated area, retinal vessels could be seen clearly outlined. There were numerous punctate hemorrhages, especially along the superior temporal vessels and in the region of the gray inner end of the upper arc.

In the left eye, the media were all clear, except for a few small vitreous opacities. The retinal vessels also showed some sclerotic changes. The fields of vision in both eyes showed a normal peripheral field. In the right eye, there was a large central scotoma.

This retinal degeneration occurred in a man in whom no general physical condition could be found as a possible etiologic factor.

The inner, upper portion of the degenerating retina was evidently the most recent part to be affected and it was in this region where most of the punctate hemorrhages were noted and in which the tortuosity of the veins was most marked.

Comment. Many other reports have noted the occurrence of hemorrhage as the probable beginning of the circinate degeneration, and it is probable that some degree of arteriosclerosis occurs in the majority of the cases occurring in elderly people. The fact that an occasional case is seen in children and young adults would indicate that, at times, factors other than arteriosclerosis are responsible.

In the case here reported, hemorrhage and sclerotic changes in the retinal vessels are the predominant findings, and it seems reasonable to assume that they were the prime factors in producing the degeneration noted.

Course. This patient was seen again in

May, 1948, approximately one year following the original examination. The only change to be noted in the period of one year was an increase in the density of the white portion of the upper arc of the degenerating area. This change is further evidence that the upper arc is the portion of the retina most recently involved. Also that
Fig. 1 (Henderson). The white, degenerated area is not elevated above the surrounding retina but retinal vessels course evenly across its surface.

hemorrhage was of prime importance in the etiology, since it was in the proximity of this area in which most of the punctate hemorrhagic spots were noted.

DISCUSSION

In making a diagnosis in this case, it is necessary to rule out the possibility of angiomatosis retinae, which may be found in a great variety of retinal manifestations and which is sometimes accompanied by a circinate degeneration.

The appearance of the upper temporal vessels (fig. 1), which were described as resembling clusters of grapes, leads one to a careful inspection of the fundus periphery for other evidence of angiomatosis.

There are no sacculations or aneurysmal dilatations, such as described by Duke-Elder and others.

The white, degenerated area is not elevated above the surrounding retina but, as can be seen from the photograph, retinal vessels course evenly across its surface. The retinal vessels, other than those seen in the upper temporal area, while considerably dilated, show no evidence of aneurysmal dilation and none of them end in a sacculation.

The preponderance of reports of angiomatosis are in young adults, the preference being in the third decade.

In the present case, there is definitely a lack of the extensive and marked vascular changes, or evidence of tumor formation or massive retinal exudate, which are more characteristic of angiomatosis.

SILVER NITRATE CAUSING DACRYOCYSTITIS

Peter Sykowski, M.D.
Schenectady, New York

For the prophylaxis of ophthalmia neonatorum, silver nitrate instillation is a routine procedure. In ophthalmic textbooks, old and new, no mention is made of silver nitrate solution as an etiologic factor in the production of dacryocystitis in cases of nasolacrimal duct obstruction. That such a factor exists is suggested by several observed cases.

REPORT OF CASES

CASE 1

Bilateral nasolacrimal duct obstruction. T. R. was seen at the age of 5½ weeks. Silver nitrate, 1 percent, was instilled following birth. On the fifth day, acute purulent discharge in the right eye occurred, followed by a similar involvement of the left eye. In both eyes there was lid edema, marked conjunctival injection, profuse purulent discharge, purulent expression from the puncti, and an extensive superficial central keratitis. Bilaterally, the ducts were obstructed. Dilatation of the puncti, irrigation with penicillin, and probing of both ducts established drainage. The course thereafter was uneventful.

CASE 2

Unilateral nasolacrimal duct obstruction. P. M. was seen at the age of 7 days. Silver nitrate, 1 percent, was instilled after birth. On the fifth day following birth, the left eye became involved. Lid edema, marked purulent discharge, purulent expression from the punctum, and several small corneal punctate staining areas were observed. The nasolacrimal duct was not patent. The course after probing of the duct was unremarkable.

Ten additional unilateral cases were observed within seven days after birth. Except for the absence of corneal involvement, all were similar in severity with uneventful courses following reëstablishment of duct patency.

CASE 3

Unilateral duct obstruction. P. A. was seen at the age of 7 months. Epiphora of the right eye was present shortly after birth. Signs of duct inflammation were at no time present. Irrigation of the duct system revealed complete obstruction.

Following the irrigation, experimentally, one drop of 1-percent silver nitrate solution was instilled. On the third day, a moderate amount of silver catarrh was present, the cornea being clear. Upon irrigation of the sac, considerable white, stringy, clumpy debris was obtained through the puncti.

After probing of the duct, the course became uneventful.

COMMENT

The coincident occurrence of dacryocystitis in nasolacrimal duct obstructions alerts one to the likely implication of the nitrate of silver solution. Normally, silver nitrate solution is said to be neutralized rapidly by the chlorides in tears. A deficiency factor, influencing considerably the pathologic process —a deficiency in the defense against bacterial invasion—is the absence of tears at birth. Inadvertent instillation of strong silver solution into the eyes of newborn infants, or failure in the neutralization of the instilled drops, may form the basis of the complication.

Prophylactically, to minimize the danger to the nasolacrimal duct system, neutralization by and generous irrigation with normal saline solution should follow nitrate of silver instillation. This neutralization and irrigation would be especially desirable after use of those solutions which, unknown to the user, have increased in concentration.

It seems possible that the dacryocystitis observed in newborn infants with nasolacrimal duct obstruction may be the result of nondrainage through of the silver nitrate solution and its subsequent caustic action on the mucous membrane of the lacrimal system.

A SIMPLIFIED ASTIGMOMETER*

JAMES E. LEBENSOHN, M.D.
Chicago, Illinois

Precision in refraction requires that the axis and value of any cylinder needed be known before dealing with the spherical correction. The reverse routine, by which the sphere that gives the best vision is first determined and the weakest acceptable cylinder then added, does not assure an exact correction even under cycloplegia. The final result of such technique is not infrequently an undesigned spherical equivalent. To attain the sharpest possible focus, the correct cylinder, regardless of power or axis, must be prescribed. Toleration will ensue if compensation is provided for associated factors, such as the differential prismatic action of the lenses or persisting accommodative tone, though, or course, the patient may require some days to reinterpret the new type of imagery and "get used to the glasses."

All methods of cylinder determination have their place but one of the most generally useful is the astigmatic chart. It is invaluable in noncycloplegic and postcycloplegic refraction, and likewise is a desirable check after cycloplegic retinoscopy. Moreover, when adequate objective refraction is impossible, as in opacities of the cornea, conical cornea, and incipient cataract, the astigmatic chart often gives helpful results.[†]

The ideal astigmatic chart should be a single unit of simple design, easily handled, unsoilable, and need no computation. The projectochart cross dial, although excellent otherwise, fails in the last qualification. The correct use thereof is also rather complicated. After proper fogging, the cross is set at axes 90° and 180°. If the lines look alike either no astigmatism is present or the axis is 45° or 135°. If the vertical line is clearest, as will be assumed, the axis may be 90° or within 45° to either side. The cross is then rotated 45°. If the line at 45° is clearest, the 45° meridian must be closer to the true axis than that at 135°. As the clearer line is rotated step by step away from 90°, the difference between the two lines lessens until at a certain point both lines have the same appearance. If this position is 30°, the true axis is 45° therefrom or at 75°.

ASTIGMOMETER OF NEW DESIGN

All this computation is avoided in the dial of my design which I appropriately term "a simplified astigmometer" (fig. 1). Incidentally, the word astigmometer, though perchance unfamiliar, is in the unabridged dictionaries, the definition being "an ap-

† Illustrative cases: (a) Woman, aged 31 years. Paracentral scars left cornea. Glasses from oculist, one month old: L.E., +1.25D. sph. ⊃ —3.0D. cyl. ax. 95° = 20/30. Prescription after astigmometer test (postcycloplegic)): L.E., +0.25D. sph. ⊃ —4.0D. cyl. ax. 95° = 20/20. (b) Girl, aged 12 years. Bilateral conical cornea. Oculist reported after cycloplegic refraction uncorrectible amblyopia: R.E., —0.5D. sph. ⊃ +5.0D. cyl. ax. 10° = 20/70; L.E., —0.50D. sph. ⊃ +4.50D. cyl. ax. 170° = 20/100—1. After the astigmometer test the indicated prescription was: R.E., —1.0D. sph. ⊃ +8.0D. cyl. ax. 5° = 20/30; L.E., —5.75D. sph. ⊃ +7.0D. cyl. ax. 175° with 4.5ᐃ slab-off, 20/40. Although this would have given serviceable vision, contact glasses were advised, and an excellent result was reported. (c) Man, aged 70 years. Immature cataract, left eye. Glasses from oculist, six weeks old: L.E., +0.75D. sph. ⊃ +0.75D. cyl. ax. 180° = 20/200. After astigmometer test prescribed: L.E., +2.0D. sph. ⊃ +2.0D. cyl. ax. 10° = 20/30.

paratus for measuring the degree of astigmatism."

This new chart is durably made of vinylite plastic and hence maintains permanently its cleanliness and contrast. The axes are indicated with dual numbering completely around the dial. The outer figures are read when the dial is seen in the mirror while, with direct vision, the inner figures in parentheses are noted. The use of the dial with a mirror facilitates considerably the examination, and is highly recommended. If the convenient roller acuity chart is used, a nail at the top of the box can serve when needed to hold the astigmatic dial. In a lightly decorated examining room the general illumination is usually adequate enough for the astigmatic test. Additional local illumination when required on account of poor discrimination can be provided by the Sphero-Lux or similar examining lamp. Clinical experience has shown that the single-line cross is most suitable for the determination of cylindrical power. For the location of the axis the rotating Maddox V is more efficient since the astigmatic eye can distinguish best a difference between two lines at an angle of 60° (Verhoeff). By placing an inverted V as an arrowhead over one line the two designs are neatly combined and the astigmometric procedure is greatly simplified. The arrowhead is used to indicate the cylindrical axis; the cross to determine the cylindrical power. The chart design thus consists simply of two long lines making the cross and two short lines forming the arrowhead, all of an even 5-mm. width.

USE OF DIAL

In using this dial, the eye is properly fogged and the cross lines are presented at axes 90° and 180°. If the lines look alike and the wings also match, no astigmatism is present. But if the wings do not match the axis is 45° away on the side of the lighter wing. On shifting the arrow to this position, the arrow-line will be the blacker of the two principal lines. If, in the primary position of

the cross, the clearest line is vertical, the arrow is pointed to 90°; if horizontal, to 180°.

The attention is now directed to the arrowhead. If the wings match, the axis, as indicated by the shaft, is correct. If one wing is blacker, the arrow is rotated *away* from the blacker wing until matching ensues.
Fig. 1 (Lebensohn). A simplified astigmometer.

Where this occurs, the arrowshaft is at the *correct axis and no further computation is* necessary. To illustrate: if the clearest line is horizontal and the lower wing blacker, the arrow is moved upward until the wings look alike. Should the arrow be rotated beyond the neutral point, the upper wing will be clearer, an indication that the movement must be reversed somewhat.*

After the axes are located, the cylindrical power is next determined. The arrowhead now serves as a distinguishing mark by which the arrow-line or the other can be identified. Minus cylinders are placed at right angles to the arrow-line until this line,

* When the astigmatism is of such high degree that the wings of the arrow cannot be distinguished, the position of greatest clarity of the one line seen can still be determined. The patient usually notes a change in blackness and sharpness as this line is rotated in steps of five degrees in one or other direction.

at first the clearest, is matched by the other. If the fogging is adequate the next 0.25D. stronger cylinder should reverse the contrast.

With the cylindrical correction worn, the fog is gradually reduced in turn from each eye until no further visual improvement occurs. The position of the axis is then checked by the effect of the cross-cylinder on the Snellen letters, using the 0.12D. instrument for a corrected acuity of 20/20 or better, the 0.25D. model for a correction of 20/25 or less. If this test indicates a divergence from the axis found with the astigmatic dial, the exact axis direction can be decided by the Crisp-Stine test for which the arrow-line is ideally adapted.

CRISP-STINE TEST

The use of the Crisp-Stine test can be explained best by an illustrative case. Assume that the provisional correction is: R.E., +1.0D. cyl. ax. 15°, 20/20. With the letter chart, the cross-cylinder indicates apparently an axis of 30°. The eye is fogged 0.25D. and both the trial cylinder and the arrow-line are placed at 15°. The 0.12D. cross-cylinder is applied in the test for axis and the query is whether the wings look more alike before or after the turn of the cross-cylinder.

If the wings seem alike with the plus mark of the cross-cylinder up, *both* the arrow-line and the trial cylinder are moved to 25°, and the test reapplied. If now the wings appear matched with the plus mark of the cross-

cylinder down, the correct axis is 20°. When both the arrow-line and the trial cylinder are moved to this position, application of the cross-cylinder test will show a contrast in the wings that is reversed on rotation of the instrument.

The average fog should be about 0.75D. For cycloplegic cases the proper fog is attained by algebraic addition of the sphere and cylinder found in retinoscopy at one meter. When the arrow-line is placed in the axis of the plus cylinder, the appearance of the arrowhead will signal what change in axis position is required. In presbyopic cases, the glasses worn should be measured and the corrected acuity noted. Then a slip-on occluder is placed over one lens. The desirable fog is determined by placing over the other a plus sphere from the trial case of 1.0D. or more as indicated. In postcycloplegic testing +0.5D. sph. is added to the previous cycloplegic findings before the check for cylindrical power. Subsequently, after the fog is adequately reduced, +0.25D. sph. is added and the accuracy of the axis is checked by the Crisp-Stine test.

It is sincerely hoped that the simplified use of the astigmatic chart which I have described will help to extend the popularity that this technique deserves.

SOCIETY PROCEEDINGS

Edited by DONALD J. LYLE, M.D.

NEW YORK SOCIETY FOR CLINICAL OPHTHALMOLOGY

November 1, 1948

DR. BENJAMIN ESTERMAN, *president*

CORRELATIONS BETWEEN OPHTHALMOSCOPY AND HISTOPATHOLOGY

DR. BERTHA A. KLIEN, Northwestern University Medical School, Chicago, discussed this subject during the instruction period.

RECURRENT UNILATERAL GLAUCOMA WITH CYCLITIC SYMPTOMS (case of the month)

DR. ISADORE GIVNER presented the case of a man, aged 43 years, whose right eye had been painful and red for 10 days. Past history showed recurrent attacks of similar nature. A diagnosis of glaucoma had been made and the patient had used pilocarpine during the previous attacks. The patient stated that for many years he had had a fever in the afternoon, fatigue not related to exercise, and attacks of diarrhea. He had spent time on a farm many years ago where unpasteurized milk was drunk. X-ray studies of the chest and the Wassermann test were negative.

Examination of his eyes revealed that the right pupil was larger than the left, and there were many keratic precipitates on the posterior surface of the cornea of the right eye. The intraocular pressure was 37 mm. Hg (Schiøtz) in the right eye and 20 mm. Hg in the left. The peripheral fields were normal and the blindspot of the right eye was enlarged. Six days later, after using pilocarpine (2 percent) 3 times a day, the tension was 25 mm. Hg in the right eye. Following skin testing for brucellosis, 8 days previously, all keratic precipitates disappeared. The tension of the right eye was 18 mm. Hg with and without pilocarpine. The patient discontinued drops and the tension remained at 18 mm. Hg, and vision was 20/15, with no symptoms.

Dr. Givner said that he wished to submit the following questions for discussion:

1. He asked Dr. Conrad Berens, what is the relationship, if any, of systemic disease to primary glaucoma?

2. He asked Dr. Harold Harris whether the evidence cited was sufficient to establish a diagnosis of brucellosis?

3. He asked Dr. Adolph Posner if he felt that this was a case of glaucomatocyclitic crisis described by Posner and Schlossman; if so, what is its position in the classification of glaucoma?

Discussion. DR. CONRAD BERENS replied to the question that undulant fever has been regarded as a cause of chronic uveitis by many investigators, notably by Orloff, who reported two cases of undulant fever with extensive ocular complications, and produced experimental keratitis, uveitis, and neuro-retinitis in guinea pigs by inoculations with Brucella abortus. Green also observed 4 cases of undulant fever, and collected from the literature 28 additional cases with such ocular conditions as keratitis, uveitis, retinitis, and optic atrophy.

In studies at Cornell University, agglutination and skin tests for undulant fever were carried out on 57 patients. Because it is often difficult to make a clinical diagnosis in the subacute or chronic forms of undulant fever by the isolation of brucella organisms, immunologic procedures, such as agglutination, intradermal or complement fixation tests, and opsonocytophagic reactions are used. The interpretation of these tests were clarified in 1933 by Huddleson, Johnson, and Hammann and more recently by Harris. Since the intradermal and agglutination tests were considered to be the most reliable

tests for determining the existence of brucella infections, these tests were used at Cornell University.

Agglutination and intracutaneous tests were made on 25 patients with uveitis, 32 with other inflammatory eye diseases, and 6 with noninflammatory ocular lesions. Only one patient with chronic conjunctivitis had a positive agglutinin titer of 1:40; the intracutaneous reaction, however, was negative.

Of 57 patients, 3 had positive skin tests —2 with uveitis, and 1 with endophthalmitis. These patients were known to have used raw milk in their diet. The fact that the large majority of the tests were negative indicates that Malta fever did not play a significant role in this group of patients. However, most of the group were residents of a metropolitan area where only pasteurized dairy products were used.

Since these studies were made, Dr. Harris has examined many patients and, although some have apparently benefited from treatment with brucella antigen, only two have had severe ocular reactions. Dr. Berens said he believed that these two cases were quite certainly caused by brucellosis.

The last patient, who had bilateral uveitis, had a very severe ocular reaction. The vision was reduced to hand movements in the right eye and 10/200 in the left eye two days after a small dose of brucella antigen. This patient's condition did not respond to 25 gm. of dihydrostreptomycin. Dihydrostreptomycin is considered to be one fourth as toxic for the eighth nerve as the ordinary streptomycin and the patient has had no unpleasant symptoms or reactions.

After giving this treatment over a period of 10 days, combined with three intravenous injections of typhoid-H antigen, the anterior chambers of both eyes were aspirated and, two days following this treatment, there was considerable improvement in the left eye but the right eye gained little, if any, in vision or field. Following two blood transfusions, both the right and left eyes improved.

In spite of the fact that there was no specific proof that the treatment with brucella antigen was specific in any particular case, there were patients who had marked improvement after receiving brucella antigen. Therefore, for patients who show positive tests for brucellosis by experienced observers, the treatment with brucella antigen certainly is to be considered a worthwhile addition to our armamentarium in treating this disease.

What effect the intradermal testing had in apparently curing Dr. Givner's patient is difficult to say. However, Dr. Berens said that, in his experience, the cure of chronic uveitis by a single treatment with any antigen or by any other method has never occurred, although the first or second intradermal injections often cause a marked improvement. Dr. Berens asked Dr. Givner whether he thinks that this patient may have had so-called primary glaucoma for several years and that this attack was merely a subacute attack of uveitis from some cause other than brucellosis in a patient who had had recurrent attacks of glaucoma.

However, the fact that in 38 of 437 eyes the pathologic diagnosis was uveitis and the clinical diagnosis was chronic primary glaucoma makes one suspect that we often fail to recognize glaucoma as secondary to uveitis. The history and Dr. Harris's tests seem to be highly suggestive of the correctness of the diagnosis, but as in many cases it is difficult to say whether nature or our treatment was responsible for affecting a cure.

Another point in this case is unusual and that it is the almost immediate control of the tension with a 2-percent pilocarpine solution. Dr. Berens said that he usually has to try homatropine and cocaine and alternate these drugs with pilocarpine and the use of neosynephrin. In chronic or recurrent cases it is usually necessary to inject nonspecific protein and follow aspiration with atropine before tension is controlled. This seems to be another point in favor of the possibility

of a subacute attack of uveitis, not necessarily due to brucellosis.

DR. HAROLD HARRIS said that this man had an ocular condition which could be caused by a Brucella allergy. There was a history of ingestion of raw milk prior to 1915. About 1927 he began to have afternoon fever of unknown origin, accompanied by fatigue. In May, 1948, tests for brucellosis showed the following significant findings: Slight relative lymphocytosis with a total white count of 6,800, a so-called positive opsonocytophagic reaction, and a very weakly positive skin test. All other tests were negative. Eight days after skin testing all intraocular signs had disappeared. Seventeen days after the first opsonocytophagic test, a second test showed a moderate increase in phagocytosis of Brucella.

The evidence was insufficient to establish or rule out a diagnosis of brucellosis. However, it is not uncommon for pathologic processes of various types to clear up rapidly following the desensitizing effect of intradermal Brucella antigens, as may well have happened in this patient. Prolonged observation would be necessary, in view of the equivocal nature of the laboratory data, in order to clarify the diagnosis.

DR. ADOLPH POSNER said that this case is interesting because it opens to discussion the basic question: What is the nature of glaucoma, on one hand, and of cyclitis, on the other.

Glaucoma is generally classified into primary and secondary. Clinically such a classification is of little use and serves to stifle further thinking and research. To revert to the case presented, Dr. Posner posed three questions to be discussed:

1. Is brucellosis an etiologic factor?
2. Is the glaucoma primary or secondary?
3. How is the cyclitis related to the glaucoma?

Dr. Posner said that there was little he could add to the discussion given previously on this question except to mention that he had observed very similar clinical cases who gave negative results to brucellosis tests as well as to all others.

The second question loses much of its significance when it is realized that we have adopted arbitrary criteria in classifying glaucoma into primary and secondary. It is only by maintaining an open mind and by carefully observing and analyzing all the delicate nuances of each individual case that we can hope to learn more about the many different diseases which we include under the generic term of "glaucoma." By such a discriminating study, we may ultimately break down this heterogeneous group into several clinical entities.

One such entity, represented by only a small number of cases, appears to have been isolated by Barkan, Sugar, and Kronfeld as "narrow-angle glaucoma." The acceptance of "narrow-angle glaucoma" as an entity does not imply that glaucoma should be classified into narrow- and wide-angle glaucoma.

Wide-angle glaucoma still remains a heterogeneous group of diseases of unknown etiology and the term is therefore meaningless.

In May, 1947, Dr. Posner said that he and Dr. Schlossman presented a group of 9 cases similar to the one described by Dr. Givner. This was believed to be another clinical entity and was called "the syndrome of recurrent glaucomatocyclitic crises." Dr. Posner said that he felt that the case presented belongs to this group.

The third question, that of the relation between the glaucoma and the cyclitis, has not been fully elucidated. That a relationship does exist is apparent from the fact that the keratitic precipitates disappear soon after the subsidence of the ocular hypertension. Both the glaucoma and the hypertension may be a result of an increased permeability of the capillaries in the ciliary body, or to a change in the ciliary epithelium itself. It may be related to an allergic response, although local and systemic administration of the antiallergic or antihistaminic drugs have thus far failed to produce a significant response.

Dr. Posner said that he agreed with Dr. Berens that pilocarpine does not always help, and other drugs may have to be tried. He said that he has never had to resort to paracentesis or other forms of surgery.

In these cases it is possible for keratitic precipitates to appear occasionally without a concomitant rise in ocular tension. In some of the cases, individual attacks of glaucoma have been noted in which cells and keratitic precipitates have remained absent. Such attacks assume all the earmarks of primary glaucoma and have been treated as such without bad effects.

This entity thus takes on an importance out of proportion to its actual incidence. It may well be that certain cases of primary glaucoma are related to this syndrome, so that it may be regarded as an intermediate link between primary and secondary glaucoma.

General discussion. Dr. Ludwig von Sallmann said that he felt that this case belonged to the group of cases known as recurrent glaucomatocyclitic crises. He suggested that the use of antihistaminics or pituitrinlike drugs might be beneficial. He said that Dr. Givner did not mention whether this case had attacks of cyclitis with cells in the anterior chamber without increased tension and at other times had a rise in tension without appearance of cells in the anterior chamber. He said that he agreed with Dr. Posner's views on the classification of primary and secondary glaucoma.

Dr. Frank Vesey asked why the investigation of this case was limited to brucellosis and whether any tests had been done for tuberculosis.

Dr. Arthur A. Knapp asked whether there was any systemic disturbance, whether an ear, nose, and throat examination was done, and whether the sphenoids had been irrigated.

Dr. Benjamin Esterman asked whether this case could be one of simple glaucoma with coincidental uveitis, and whether any provocative tests were done.

Dr. Adolph Posner replied that to determine whether it is primary glaucoma it is necessary to observe the case over future attacks. The provocative tests, water tests, and Lambert-Bloomfield tests give only positive results in simple glaucoma. Homatropine and dark-adaptation tests give positive results in narrow-angle glaucoma. This does not seem to be a case of narrow-angle glaucoma.

Dr. Isadore Givner said that he had presented only the positive findings in describing this case. X-ray studies of the sinuses and teeth were negative, and there was no infection of any kind found. X-ray studies of the chest to eliminate the possibility of tuberculosis were made and proved to be negative. The sphenoids were not washed since there was no indication for such a procedure, and the angle was perfectly normal.

CLINICAL AND HISTOPATHOLOGIC ASPECTS OF ANGIOID STREAKS

DR. BERTHA A. KLIEN, Northwestern University Medical School, Chicago, (by invitation) said that the main fascination of histopathologic studies lies in the ultimate possibility of finding explanations for all clinical manisfestations of disease. No other condition lends itself more readily to the correlation of a great variety of clinical and histologic phenomena than angioid-streak formation, mainly because of two circumstances. First, the clinical picture is characteristic and the clinical diagnosis definite from the earliest stage of just a few streaks around the optic disc to the advanced lesion with loss of central vision due to the disciform macular degeneration. Second, the course of the disease is very chronic, lacking the incidental tissue reactions of acute and subacute processes, every phenomenon being inherent in the pathogenesis of the disease.

The various phenomena occurring with angioid-streak formations are most easily discussed under two headings: (1) Find-

ings, which underlie clinically visible streak formation; (2) findings that underlie the peculiar appearance of the remaining fundus which is present in all advanced cases of angioid streaks and which consists of diffuse yellowish and diffuse opaque grayish discolorations.

Clinically, the earliest streaks are reddish brown with sharp, ragged outlines. Choroidal details are often visible within the broadest portions. Histologically, they are simple breaks in Bruch's membrane, rendered visible by the opacification of this membrane through elastic degeneration and calcification. Pigment epithelium and choroid are intact.

Old streaks often appear more yellowish or have yellowish-white accompanying lines. Histologically, many of the old defects of Bruch's membrane are filled with fibroblastic granulomas, which have formed around displaced, calcified fragments of Bruch's membrane. Other breaks are accompanied by linear crests of new tissue, which often undergoes hyalin degeneration. Injury of capillaries by sharp, calcified fragments of the membrane often leads to hemorrhages.

The pathologic process underlying the diffuse opaque yellowish or grayish areas consists in extensive new formation of a cuticular substance similar to the cuticular portion of Bruch's membrane but many times thicker. These cuticular deposits are often found over multiple breaks of the membrane, as if nature had attempted to preserve its continuity, so necessary to a normal pigment epithelium. The absence, presence, or hypertrophy of the pigment epithelium over these cuticular deposits produce their varied clinical appearance.

In the late stages of the disease the macular area is invariably occupied by a lesion, which has the typical clinical and histologic appearance of a disciform degeneration. The causes for the breaks in Bruch's membrane, however, are obvious, while they are still obscure in the Kuhnt-Junius type.

The pathogenesis of angioid streaks is based upon an abnormal fragility and opacification of Bruch's membrane. The fully developed picture, however, represents not only the visible ruptures of this membrane but also the multiform end results of irritation of pigment epithelium and choriocapillaris by the sharp, calcified edges and fragments of the broken membrane.

Discussion. Dr. A. L. Kornzweig asked about the various types of degeneration of the macula, and whether the pathology is the same.

Dr. Klien replied that the pathology was the same except for the appearance of Bruch's membrane. In angioid streaks the membrane stains black.

OCULAR PATHOLOGY IN DIABETES

DR. SAMUEL GARTNER said that diabetes is an important cause of visual impairment and blindness. The survival of more old people has increased the numbers suffering from this disease and insulin has prolonged their lives, so that we now see many more diabetics with eye lesions. The incidence of diabetic retinopathy increases with duration and severity of the disease regardless of the best modern care with diet and insulin, which does not prevent its onset and extension. A formula has been made to forecast the development of retinopathy.

Dr. Gartner described the pathology of diabetic retinopathy. There are hemorrhages, exudates, and cysts associated with extensive vascular damage.

All the cases examined showed some sclerosis of the arteries. Endothelial proliferation with canalization was found frequently in arteries and veins. Capillary disease was manifest by the formation of capillary aneurysms and capillary occlusions by endothelial proliferation. Rubeosis iridis probably follows the slow occlusion of the central retinal vein by phlebosclerosis.

Bernard Kronenberg,
Recording Secretary.

LOS ANGELES OPHTHALMOLOGICAL SOCIETY

September 2, 1948

Dr. William Endres, *chairman*

ALLERGY IN OPHTHALMOLOGY

Dr. Charles Petitt (by invitation) gave a comprehensive presentation of allergy as related to ophthalmology. The causes of inflammation are numerous and variable and depend on the rate of development of the reaction, its duration, and the release of substances such as histamine by the agent.

The histologic classification of lesions in allergy may be divided into two groups. The first necrotizing, in which there is some degree of necrosis. Parenchymal cells are present and eosinophilia is rare. Cincophen poisoning is an example of acute allergic necrosis. There may be either organ specificity or cell specificity such as anaphylaxis.

The second group are anaphylactoid or exudative reactions of which urticaria is an example. These are characterized by rapid onset, short course, and rapid regression. Secondary changes, as seen following any inflammation, are present. Cellular exudates, usually neutrophilic, are present but, if the condition is prolonged, eosinophilia predominates.

Eosinophilia is not pathognomonic of allergic states. Fibrinoid necrosis, which is focal and sharply delimited, such as periarteritis nodosa, may be present. This may or may not be on an allergic basis. Anaphylactoid reactions may follow injection of foreign serum. Rheumatic fever, which is a colloid disease, may be on an allergic basis since it is well known that the Ashoff nodule can be experimentally produced.

Granulomatous diseases in which tumorlike nodules are present are the result of inflammation. Examples of this are foreign-body reactions and sarcoidosis. There is no necrosis present in these conditions.

Allergic granulomas are characterized by central necrosis. These may be divided into two types: (1) The tuberculoid group which is caused by well-known agents such as tuberculosis, tularemia, mycosis, and brucellosis. These show positive skin tests to the causative agent. (2) Rheumatoid diseases of which there is no known etiology or positive skin test. Most rheumatoid diseases can be experimentally produced.

In vernal catarrh the diagnostic criteria are plaques in the conjunctiva especially superiorly. These plaques are usually pale and are not red and injected. The fornix is not usually involved and, on section, lymphocytic and fibrous tissue are seen. Eosinophilia are present in conjunctival secretions and the bacteriologic findings are the usual conjunctival inhabitants.

The disease follows a seasonal incidence usually occurring in the warm months—more often in children and especially boys. It is interesting to note that the seasonal incidence does not correspond with the seasonal incidence of pollens. Food sensitization has not been established and the picture, histologically, is not consistent with allergic manifestations. These patients rarely show positive skin tests and there is no greater incident in allergic than in nonallergic individuals.

The speaker did not believe that vernal catarrh is due to allergy nor did he believe that it was due to infection. Vaccine therapy has been of no help whatever. There are many types of conjunctivitis which are allergic and are due to dust, yeast, foods, and so forth.

In treatment, radium will alter the inflammatory states. If the allergen is given properly, a desensitization usually occurs and the condition is at least temporarily controlled.

Daniel B. Esterly,
Secretary.

AMERICAN JOURNAL OF OPHTHALMOLOGY

Published Monthly by the Ophthalmic Publishing Company

ELECTROPHYSIOLOGY

In 1849, Emil du Bois-Reymond placed the anterior and posterior poles of a vertebrate eye between two electrodes connected to a galvanometer and found that, independent of illumination, a current passed from the cornea to the fundus of the order of 6 millivolts. Since this demonstration of an electrical response from the eye, a century of zealous study has been devoted to the phenomenon.

Du Bois-Reymond, although of Swiss-French extraction, was born and educated in Berlin. Like his fast friend, Helmholtz, he was inspired by the illustrious teacher, Johannes Müller. Humbolt, in 1841, read a report of some simple experiments in animal electricity and suggested to Müller exploration of this field. Müller handed the problem to du Bois-Reymond, whose investigations continued for the next 40 years. After seven years, then aged 30 years, he published the first of his celebrated volumes on "Researches in Animal Electricity." At the death of Müller, 10 years later, he was awarded the Chair of Physiology at the University of Berlin.

The action current of the retina, now

called the electroretinogram, was discovered in 1866 by Holmgren, and simultaneously by Dewar and McKendrick of Scotland whose paper was actually in print when Holmgren's article was published. The Scotch investigators later observed, in 1873, that the invertebrate eye with its erect retina has a resting potential of the opposite sign to that of the vertebrate eye, signifying that the electric response of the eye, at rest as well as in action, is maintained by the visual cells.

The sensitive capillary electrometer enabled the Englishman Gotch to obtain, in 1904, the first electroretinogram that embodied all the features now known. The technique of valve amplification, which is now standard practice, was introduced by the Americans, Chaffee, Bovie, and Hampson, in 1923, and the retina was the first sense organ to be thus studied. By its means, Adrian demonstrated, in 1928, that an optic-nerve fiber responds to increased stimulus by increased rate of discharge, the size of the impulse remaining constant.

The analysis of the polyphasic response of the retina to light was initiated by Granit in 1932. His experiments with selectively acting agents proved that the vertebrate electroretinogram is built from at least three distinguishable components.

In 1938, Hartline isolated single fibers of a vertebrate optic nerve and demonstrated that all do not respond to light in the same way, and that a large number of visual units evidently respond only to changes in intensity. Shortly thereafter, Granit advanced Hartline's work by placing micro-electrodes directly on the retina, and so determined the color sensitivity of small groups of retinal elements—experiments which resulted in his modulator-dominator theory of color vision.

The electroretinogram affords a sensitive objective expression for the effects of light upon the retina. Even the luminosity curve is quantitatively reflected by the electrical response, as Granit revealed in 1943.

Among the contributors to the study of human electroretinograms are Karpe of Sweden, Spellberg of Russia, Amsler of Switzerland, and Adrian of England. Adrian has been his own subject in most of his work, operating the instruments by strings led into the dark room. The clinical application is illustrated by a case of Amsler's with variable concentric contraction of the visual field following trauma. Since the electric responses corresponded to a normal field he concluded that the contraction was due to a functional block at the cortical level.

The variation of the resting potential that occurs in the eye movements of reading can be recorded through electrodes placed at the external canthus of each eye. The graph closely duplicates the photographic record, but the electro-oculogram has the advantage of requiring no restraint nor the presence of a glare light. This method, perfected by Miles in 1939, was recently utilized by Carmichael and Dearborn in the most comprehensive study of reading and visual fatigue yet made. James E. Lebensohn.

THE FRENCH OPHTHALMOLOGICAL SOCIETY

The French Ophthalmological Society opened its 56th annual congress in 2,000-year-old Paris, at 8:30 a.m., on Sunday, May 22, 1949. The meeting lasted the customary six days. The mornings were devoted to papers and discussions and the afternoons to visiting hospitals.

Some 400 members attended, out of a total membership of 1,200. Strange to say, the French are far in the minority, numbering only 500, the other 700 members being foreigners. It is never possible for all to be present at any one meeting.

Twenty-three countries were represented: France, England, Ireland, Belgium, Switzerland, Italy, Holland, Spain, Portugal, Yugoslavia, Turkey, Greece, Syria, Lebanon, Iran, Poland, Denmark, Sweden, Luxemburg, United States, Colombia, Brazil, Argentina, and the town of Gibraltar.

The symposium of the congress, on uveitis with hypertension, was opened by Marcel Kalt. The discussers were J. François who spoke on gonioscopy in hypertensive uveitis; J. D. Blum and S. Forni on results of cyclodiathermy coagulation on the surface in secondary hypertensions; Hambresin on what collyria should be employed in hypertensive uveitis; Florian Verry on the aqueous humor in the hypertensive syndrome of uveitis; and Nectoux on the action of metamethylarmine (M.M.P.) on the eye and its employment in hypertensive uveitis.

The masterly review of the entire subject by Kalt and the gracious manner in which he replied to the discussers created a most favorable impression.

J. Q. Barraquer read a paper on postoperative complications of keratoplasty and Arruga one on the mechanical role played by retrobulbar injection in operations for strabismus. (It was during the meeting that Arruga was awarded the Gonin medal by the International Council of Ophthalmology then in session in Paris.) Valiere-Vialeux's paper on liquefaction of the vitreous and the loss of it in cataract extraction causing collapse of the globe was particularly instructive. Kirby's demonstration (using films and projection) of his technique for intracapsular extraction was excellent.

In the more than 60 presentations, almost every field of ophthalmology was touched on, surgery predominating. The proceedings were so efficiently conducted that no precious moment was lost. As a rule each discusser was already on the steps to the platform or actually on it before the speaker had concluded his last sentence. Nothing could be more stimulating and educational than to attend a session of the French Ophthalmological Society.

For the afternoons some 15 hospitals had prepared special operative and clinical programs which had all been posted the first day of the congress.

All through the week, in a large room under the meeting hall, there was held an exhibit, surprisingly fine for the times, of surgical instruments and various appliances gathered from many countries of Europe.

The afternoon for the traditional outing in the country fell on the third day. This time it was by bus to Malmaison and its lovely gardens, so reminiscent of the glorious days of the Consulate and the sad hours of the Emperor's abdication. On the way back to Paris a rarely enjoyable hour was passed in Villenes at Dr. Gabriel Renard's country place, hidden away from the roadside, in its lovely grounds, by trees and shrubs.

The banquet took place in the evening. Two hundred and eighty-two guests sat down at table. Paris still shows scars from bullets and fires of the recent conflict, especially around the Place de la Concorde, but gastronomically the recovery has been complete, as was borne out by the delicious dinner and the food everywhere. Prendront la parole à la fin du dîner, the president of the banquet, Sir Stewart Duke-Elder, made a most appropriate speech, as did Dr. Appelmans, Dr. Alvara, Dr. Streiff, and Dr. Rossi who sat at his table. The secretary general, Dr. Edward Hartmann, on whose shoulders had fallen the brunt of the whole congress, replied in the name of the society. His speech was on a very felicitous note that brought into the scene, one by one, each country that was represented.

Concerning the beginning of an organization that has met with well-nigh unprecedented success and world renown it will be informative to turn the pages of ophthalmology back to the year 1857 when the first International Ophthalmological Congress was held. Because it met at long intervals and at great distances and because the evolution of ophthalmology was proceeding so rapidly, the desirability of forming national societies for more convenient discussions arose which in turn have led to local societies. The German Ophthalmological Society of Heidelberg came into existence in

1863, the American Ophthalmological Society in 1865 and the Ophthalmological Society of the United Kingdom in 1880. The French Ophthalmological Society, at its foundation in 1883, was patterned after the Heidelberg society. However, it was to be an organization composed exclusively of French-speaking oculists. The Germans, when they heard of the new society, in sending their congratulations, made it known that, although their mother tongue was different from the Latin, they nevertheless hoped that the French would extend to them the hospitality of their meetings.

The granting of this desire was destined to have a far-reaching effect. At the second congress, in 1884, no less personages than Art and Hirschberg of Berlin, Bowman of London, Becker of Heidelberg, Donders of Utrecht, Horner of Zurich, Pflüger of Berne, and Reymond of Turin were numbered among the 112 members present. Today, among those from afar, are 21 members from the United States.

The society, like so many others, is but the lengthening shadow of one man, Chibret, of Clermont-Ferrand, whose initiative created it and who sent out the call for its first meeting. It always sits in Paris. Only twice has it gone elsewhere. In 1923, it met in Strasbourg at the centenary of Pasteur and, in 1925, in Brussels where at its opening session it was honored by the presence of her Majesty the Queen.

The society is governed by a committee of 12—5 members from Paris, 6 from the French provinces, and 1 from a foreign country. There is no president but instead a secretary general. It is often called the most international of all the national societies.   Bernard Samuels.

ACTA OPHTALMOLOGICA POLONICA

A Polish journal of ophthalmology has been launched. It is a quarterly publication called *Klinika Oczna, Acta Ophtalmologica Polonica,* and is a most promising journal. The paper is not nearly so good as that which we use and the half tones, although adequate, are certainly less crisp than they might be. But the intellectual content, on the other hand, has great merit. The scholarly articles in Polish are also presented in a very extensive abstract in English or French. The first articles in the first of the two issues that have been received report the work of Wilczck Marian on the lamina cribrosa which also appeared in the *British Journal of Ophthalmology.* There are also articles on refraction, physiologic optics, glaucoma, streptococcus, and on lesions of the cornea and retina.

The new journal is a welcome addition to ophthalmologic literature. We congratulate our Polish colleagues and wish them success in this fine venture.   F. H. Haessler.

OBITUARIES
ROBERT J. CURDY
(1868-1948)

Robert J. Curdy was born January 25, 1868, at Humbolt, Kansas. He was the son of William Wilson Curdy and Helen Sackett Curdy. There were two brothers and one sister. He received his early education in the public schools of Humbolt, Kansas, and then attended the College of Liberal Arts and Sciences at the University of Kansas, 1883 to 1886. He received the degree of Doctor of Medicine from Washington University in 1895, and completed the postgraduate course in 1896 (*cum laude*). He then entered the office of Dr. John Green, Sr., and was his assistant for three years. The following year he spent in study and in working in several leading European clinics. On his return to the states, Dr. Curdy opened his office in Kansas City, Missouri, for the practice of ophthalmology and remained in active practice to the day of his death, December 15, 1948.

Dr. Curdy became a member of the

American Ophthalmological Society in 1906 and was made emeritus member in 1938. He was a past president of the Kansas City Society of Ophthalmology and Otolaryngology. He was also a fellow of the American College of Surgeons and the American Academy of Ophthalmology and Otolaryngology. He was a member of the staffs of St. Luke's, Research, Municipal, St. Margaret's, and Children's Mercy Hospital and remained active in the clinic of the latter until 1946.

Dr. Curdy published many scientific articles and was the first to advocate equal recession and resection in horizontal strabismus. He was also first to advocate the external approach in narrow-angle glaucoma, and designed a special knife for the purpose of performing the Lagrange sclerectomy by the external approach.

He was married to Ann Richardson Hall on November 3, 1906. Two daughters, Helen and Isabel, and Mrs. Curdy, survive.

Robert Curdy was a keen clinician and was unsurpassed in presenting and discussing the differential diagnosis in an obscure case. He was one of those rare individuals who knew no enemies, either in or out of the profession, and never once was he known to have said an unkind word of anyone. Robert Curdy has died but his memory and ideals will live on in the minds of us who have been privileged to have known him intimately. Albert N. Lemoine.

DAVID L. TILDERQUIST
(1872-1948)

With the passing of David Tilderquist on September 26, 1948, the medical profession lost one of its most unassuming but devoted ophthalmologists and the people of the Northwest lost a well-beloved friend and skilled physician, who had served them for 44 of his 76 years. Dr. Tilderquist will always be remembered for his humble and kindly manner, his generosity, his unswerving loyalty to all that was good, and for an integrity of character which endeared him to everyone who knew him.

He was born in Vasa (Goodhue County), Minnesota, on October 22, 1872. He lived and worked on the parental farm, attending the local public schools and then Gustavus Adolphus College in St. Peter, from which institution he was graduated in 1894. After teaching in the public and parochial schools in Goodhue County and at Hope Academy in Moorehead, Minnesota, for six years, he entered the University of Minnesota with a keen desire to become a chemist. His brother, William, a mining engineer, prevailed upon him to continue his studies in medicine rather than chemistry and, in 1903, after he was graduated from the University of Minnesota, he spent a year interning at Swedish Hospital in Minneapolis—in the days when many medical students entered practice without benefit of internship. Dr. Tilderquist spent much time in the pathologic laboratory doing independent study.

He established a general practice in Duluth, in 1904, which, from the early days, taxed even his great capacity for long hours of work. He studied abroad first from 1910 to 1911, when he specialized in ophthalmology and otolaryngology, and then again in 1924, when he took further work in Vienna.

Dr. Tilderquist held a number of hospital staff appointments during his long years of service in Duluth, including that of chief of staff at St. Luke's Hospital, and chief of the Eye, Ear, Nose, and Throat Service at St. Mary's Hospital. During the past 25 years he had taught the nurses' classes in ophthalmology at St. Luke's Hospital and annually offered awards for scholarship in therapy and bedside nursing. He was instrumental in establishing and running the ophthalmologic service of the Methodist Dispensary for many years and later assumed more than his share in the ophthalmic work of the Miller Memorial Hospital Dispensary, when younger men were not available to carry on the service.

In 1926, Dr. Tilderquist was president of the Minnesota Academy of Ophthalmology and Otolaryngology; at the time of his death he was serving as its vice-president. He was a member of the American Academy of Ophthalmology and Otolaryngology, a member of the American Medical Association, the American College of Surgeons, the Minnesota State Medical Association, and the St. Louis County Medical Society. He was a diplomate of the American Board of Ophthalmology and the American Board of Otolaryngology.

He was an ardent student and followed the ophthalmic literature closely. His mind was a scholarly one and his reading was not aimless. In addition to following the current literature, he always pursued one or more definite lines of study. He wrote few articles, largely because of his extreme modesty. For many years he found time to abstract Scandinavian ophthalmic literature for the AMERICAN JOURNAL OF OPHTHALMOLOGY, whose editor was his close friend, Edward Jackson. He developed a few surgical instruments, which are on the market, but of which he never spoke.

This quiet scholar encouraged studious habits in others; his was the moving spirit in the small local organization of ophthalmologists and he it was who stimulated the members to study and to make reports. He always faithfully attended the meetings of the local county society, the weekly pathologic conference, the Minnesota Academy of Ophthalmology, and the American Academy of Ophthalmology. He was always most kindly and generous to younger men, several of whom, it has been learned, he helped through medical school. He established a scholarship at his alma mater, Gustavus Adolphus, for freshmen who give promise in scientific study. In 1946, this college honored him with a special award as one of the outstanding alumni who had been of great service.

His generosity and unselfishness are typified in the letter, accompanying a research grant given to the writer, which reads in part:

"Enclosed herewith please find a gift in the interest of research. . . . You may use this fund in any way you see fit, or you may even reimburse yourself from it for expenses incurred or for losses sustained or compensate yourself for time spent on account of research done in the past.

"This fund is meant to be a help and not a burden. Therefore it does not carry with it the implication that any research must be carried out that would not otherwise have been undertaken without the fund.

"Wishing you many dividends in the form of new knowledge and much enjoyment and satisfaction. . . ."

Dr. Tilderquist gave unstintingly of himself to his patients; no matter how late the hour or how great his own fatigue, he worked patiently and carefully with each one. Colleagues, who sought his consultations frequently, did so because they felt assured an exhaustive and conscientious study would follow.

Dr. Tilderquist had the rare good fortune to experience, while he was still alive, hundreds of expressions of love and admiration, which so often go unsaid. His measure, indeed, was overflowing with the admiration, respect, and love of his colleagues and his thousands of grateful patients and friends.

A. C. Hilding.

CORRESPONDENCE

BETA IRRADIATION OF THE EYE

Editor,
American Journal of Ophthalmology:

In a recent pamphlet distributed by Dr. Harold Swanberg describing his radium-D applicator, produced by the Canadian Radium and Uranium Corporation, quotations were made from the article by Hughes and Iliff, "Beta irradiation of the eye," AMERICAN JOURNAL OF OPHTHALMOLOGY, 32:351 (March) 1949.

The results of beta radiation reported in

this article were obtained by using radon (not radium-D) applicators. The experiments and clinical results from the use of a Swanberg radium-D applicator at the University of Illinois have been reported by Dr. Fred M. Wilson at the 1949 meeting of the Association for Research in Ophthalmology.

Dr. Wilson found important differences between the effects of radium D and radon, the former showing about 40-percent effective beta output and less penetrating power. These differences are important in the practical aspects of treatment; for example, duration of treatment and ability to eliminate corneal vascularization and other pathologic processes situated more deeply in the lids, cornea, and sclera.

(Signed) William F. Hughes, Jr.,
Chicago, Illinois.

STAINING TECHNIQUE FOR
TRACHOMA INCLUSIONS

Editor,
American Journal of Ophthalmology:

In the May, 1949, issue of the JOURNAL, page 702, Lieut. V. O. Eareckson brings forward Wright's staining method as "a rapid staining technique for the demonstration of trachoma inclusions." Forty years ago I brought forward the same method for the same purpose—"A rapid method of staining the trachoma bodies of Halberstaedter and Prowazek," *Ophthalmic Record*, October, 1909. Probably the reason it did not come into general use was that it requires more careful attention to detail than does the Giemsa method.

(Signed) F. H. Verhoeff,
Boston, Massachusetts.

BOOK REVIEWS

TOXIC EYE HAZARDS. A manual prepared by the Joint Committee on Industrial Ophthalmology of the A.M.A. and the American Academy of Ophthalmology and Otolaryngology. Publication No. 494. New York, The National Society for the Prevention of Blindness, 1949. 34 pages, 10 illustrations, bibliography. Price, $1.00.

The preparation of this manual and the extensive work that went into its background excites profound admiration for all who had a part in its formation and assisted in its publication.

It is a factual, practical, and inexpensive masterpiece of great use to industry and ophthalmologists working with industrial eye problems.

Chapter I has to do with standards and tests for eye-protection equipment. It describes, as an example, a well-organized eye-protection program. Part II of the first chapter gives tables of toxic compounds and the ocular signs and symptoms they produced.

Chapter III contains an excellent description of standard emergency and first-aid procedures in chemical eye injuries, based upon the completely satisfactory results obtained from practical experience.

The manual should be read and studied by every ophthalmologist, whether interested in industrial ophthalmology or not, and by every physician employed by industry. Derrick Vail.

UEBER WERTUNG ANGEBORENER FEHLER DES FARBENSEHENS. By Georg Wilhelm Keyser, M.D. Oslo, Norway, A. W. Brøgger Press, 1943. Paper covers. 174 pages, bibliography, 2 colored plates. Price, not listed.

The problems of color vision have excited a marked recrudescence of interest in the past decade. Keyser, as a practicing ophthalmologist, is primarily concerned with the color capacity requisite for the performance of various tasks. The introductory chapters review both critically and comprehensively the contributions to our knowledge of color deficiency, from the original discovery by Dalton of his own color blindness in 1794 to the present.

Then follows a detailed analysis of the signals used in railroading, navigation, aviation, and military maneuvers. Keyser objects to the Nagel anomaloscope because it tests only foveal function, whereas he maintains that the parafoveal area, because of irradiation and dispersion, should be of principal importance in signal discrimination.

Keyser prepared a strip of color film that recorded a blinking red light in Oslo harbor. With this strip he tested men from 11 to 77 years of age, classified by the standard tests as normal or having various types and degrees of color deficiency. Only deuteranopes failed consistently in the test, calling the red light green. The anomalous trichromats named the color correctly.

He asserts that modern signal devices largely eliminate the danger of wrong interpretation by the color deficient. However, he would consider any form of color weakness as a serious handicap in medical practice, as the undue color contrast characteristic of anomalous trichromats may induce false judgments on tissues and bacterial slides.

The book is highly stimulating and suggests the need of further studies on the practical problems of color deficiency in connection with the conditions of the assigned tasks. It is to be hoped that Keyser will soon complete the English version of this work according to his original intention.

James E. Lebensohn.

How to Become a Doctor. By George R. Moon, A.B., M.A. Philadelphia, The Blakiston Company, 1949. 130 pages. Price, $2.00.

The boy or girl interested in a medical career is often at a loss for where to turn for advice on where to go for his medical education, for information about the courses given, and how to qualify to take them.

Moon has performed a much-needed task in giving this information in a compact form that is highly successful in its aims. It is a "complete guide to the study of medicine, dentistry, pharmacy, veterinary medicine, occupational therapy, chiropody and foot surgery, optometry, hospital administration, medical illustration, and the sciences."

It should be in the hands of anyone who is preparing to "become a doctor."

Derrick Vail.

Gli Antibiotici in Oftalmologia. By Antonio Grignolo. Torino, Minerva Medico Press. 321 pages, 21 figures. Price, not listed.

This thorough monographic treatment of the antibiotics is to be highly recommended to Italian readers. The author has not favored us with summaries in another European language, as have some of his countrymen, but it is arrogant to expect this from one who writes in a language which was used by perhaps the only poet who is the equal of Shakespeare. The date of publication is not stated but the bibliography contains reference to publications in 1948.

The entire subject is adequately treated. After a brief introductory statement on the nature of the antibiotics, the work on penicillin and streptomycin is extensively described and many other antibiotics are given shorter but adequate review. The preparation, titration, biologic properties, tolerance, and dosage are discussed from personal experience and on the basis of a thorough review of the literature.

Even more, extensive treatment is accorded the specifically ophthalmic experience. Diseases of each ocular tissue are discussed in detail and the merits, as well as inadequacies, of antibiotic therapy are evaluated. Each section has an extensive list of references.

F. H. Haessler.

ABSTRACT DEPARTMENT

Abstracts are classified under the divisions listed below. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

1. Anatomy, embryology, and comparative ophthalmology
2. General pathology, bacteriology, immunology
3. Vegetative physiology, biochemistry, pharmacology, toxicology
4. Physiologic optics, refraction, color vision
5. Diagnosis and therapy
6. Ocular motility
7. Conjunctiva, cornea, sclera
8. Uvea, sympathetic disease, aqueous
9. Glaucoma and ocular tension
10. Crystalline lens
11. Retina and vitreous
12. Optic nerve and chiasm
13. Neuro-ophthalmology
14. Eyeball, orbit, sinuses
15. Eyelids, lacrimal apparatus
16. Tumors
17. Injuries
18. Systemic disease and parasites
19. Congenital deformities, heredity
20. Hygiene, sociology, education, and history

2
GENERAL PATHOLOGY, BACTERIOLOGY, IMMUNOLOGY

Buschke, W. **Morphologic changes in cells of corneal epithelium in wound healing.** Arch. Ophth. 41:306-316, March, 1949.

The authors report their experiments with corneal injuries in rats and frogs. Pseudopodial extensions of the cytoplasm directed into the denuded area are seen in the basal layers of the epithelium in the early stages of healing of pinprick injuries. These pseudopods are observed particularly in pockets of the wound margin during the healing of larger injuries. Spreading and flattening of the epithelial cells, which lead to sealing off of the wound margin, occur in linear and larger lesions in the early stages. This sealing off is seen also in the healing of small injuries in the superficial layers of the epithelium.   Ralph W. Danielson.

3
VEGETATIVE PHYSIOLOGY, BIOCHEMISTRY, PHARMACOLOGY, TOXICOLOGY

Agrest, A., Roncoroni, A. J., García Badaracco, J. E., and Vidal, F. **Carbam-**inoylcholine in rabbits with partial parathyroidectomy. Arch. de oft. de Buenos Aires 23:294-297, Oct., 1948.

The authors feel that the tetany of hypoparathyroid states occurs because the hypocalcemia modifies the sensitivity of acetylcholine. Partial parathyroidectomy was performed on rabbits and carbaminoylcholine was used as an index of the activity of acetylcholine. In some hypocalcemic animals observed, the ocular tension did rise as the body contractions increased, and when calcium was administered intravenously the tetany diminished and the tension was lowered. However, as yet, it is not possible to draw any satisfactory conclusions. (4 graphs.)   Edward Saskin.

Baumann, Adamo. **First report on experimental researches in electroretinography.** Ann. di ottal. e clin. ocul. 74:375-380, May, 1948.

A suitable subject for electroretinography was found in a woman with craniofacial dysostosis whose eyeball could be dislocated so far forward that an electrode could be applied to the posterior pole of the globe. Baumann found that as the intensity of the luminous

stimulus is increased the retinal action current likewise increases up to a point beyond which further increase in the stimulus results in decrease in the action current. (References.)

Cristini, G., **The vascular action of pilocarpine, eserine, adrenalin and atropine, and their influence in primary chronic glaucoma.** Brit. J. Ophth. 33:228-242, April, 1949.

Pilocarpine and eserine do not dilate the large vessels of the iris and ciliary body but dilate the capillary bed and open new capillary districts. Although this produces an increase of the sum of resistances in the circulation, the total result is reduction of the mean capillary hydrostatic pressure and, therefore, of the ocular tension. Atropine dilates the large vessels, but does not open new capillary beds. This decreases the sum of resistances and, therefore, increases the mean hydrostatic pressure whenever the capillary bed is already impaired, as in chronic glaucoma. Adrenalin dilates both the large vessels and the capillaries and increases the circulatory bed. The result is an increase in the sum of resistances, and a decrease of the mean capillary hydrostatic pressure and of ocular tension. In acute glaucoma, however, the excessive permeability in the capillaries for plasma proteins may produce elevation of intraocular pressure.　　Orwyn H. Ellis.

4

PHYSIOLOGIC OPTICS, REFRACTION, COLOR VISION

Swan, K. C. **Pharmacology and toxicology of the cornea.** Arch. Ophth. 41:253-275, March, 1949.

This article combines literature, original research, and practical suggestions in therapy so admirably that it should be read in full.　　R. W. Danielson.

Vidal, F., García Badaracco, J., Agrest, A., and Roncoroni, A. J. **Neurocapillary test in rabbits.** Arch de oft. de Buenos Aires 23:292-293, Oct., 1948.

Carbaminoylcholine solution, 0.33 percent, was instilled into rabbits' eyes with these results: increased lacrymal and salivary secretion within three minutes, increased intestinal motility and diarrhea within five minutes, increased pulse rate, conjunctival vasodilatation, and miosis. Influence on ocular tension was equivocal. (2 graphs.)　　Edward Saskin.

Woods, A. C. **Experimental studies on the pathogenesis and treatment of ocular tuberculosis.** Brit. J. Ophth. 33:197-228, April, 1949.

The author reports on 12 years of investigation in which human strains of the tubercle bacillus were injected into the anterior chamber of rabbits. In the study of pathogenesis the influence of the number and virulence of organisms was determined. Small doses of virulent bacilli in a normal animal produce a slowly-spreading infection. A larger dose accelerates the reaction. In the immune-allergic rabbit the propagation and spread of the organisms is restrained. With a large dose the immunity is overwhelmed and the animals develop an acute destructive inflammation. In both the normal and immune-allergic animals the ocular inflammation resulting from infection approximates the degree of ocular sensitivity. Desensitization before inoculation abolishes the primary ocular reaction to tuberculoprotein, and the ocular inflammation is of low degree when the desensitization is maintained. The resistance to reinoculation was totally undisturbed by complete densensitization before inoculation. With high cutaneous sensitivity the ocular sensitivity is also high; however, ocular disease may produce great ocular sensitivity without affecting a normally low cutaneous sensitivity. The transient

immunity to re-inoculation shown by eyes that have recently recovered from tuberculosis is due to the presence of persisting macrophagic cells. Desensitization with tuberculin is accompanied by a marked decrease in manifestations of the disease. It removes the destructive factor. If tuberculin treatment is stopped the tissue sensitivity, and in many animals the ocular lesion, recur. The relatively nontoxic sulphone, promizole, has a deterrent action on the local tuberculous lesion in the immune-allergic rabbit, and when combined with streptomycin eradicates the bacilli from the infected tissue of most of the animals, and curtails their growth and virulence in the others.

DIAGNOSIS AND THERAPY

Bunge, E. **A new method for quick determination of the dominating eye.** Klin. Monatsbl. f. Augenh. 114:69-71, 1949.

An observer looking into two mirrors joined by a stick at a right angle will note double images. The image in the dominating eye is the more disturbing. The author discusses his method and compares it with others. Max Hirschfelder.

Dattner, B., Distelheim, I. H., and Maltzer, L. **BAL in arsenical optic neuritis.** New York State J. M. 49:190-192, Jan. 15, 1949.

BAL has been found to be of value in removing arsenicals and heavy metals from living tissue. Pentavalent arsenic was used for pemphigus vulgaris and toxic optic neuritis secondary to the treatment was relieved by the intramuscular use of BAL. The dosage used was 0.5 cc. intramuscularly, increased by 0.5 cc. every three hours until 2 cc. is reached. Ephedrine sulphate 0.24 gm. is given orally one half hour before each dose and at the time of injection of BAL it is re-

peated. BAL must be used with caution. It produced a toxic psychosis in this patient during the course of treatment.

H. Weinberg.

García Notico, F. **New technique for the inclusion of muscles on a spike, in enucleations.** Arch. de oft. de Buenos Aires 23:216-219, Sept., 1948.

The plastic prosthesis has a central cone behind, which extends back into the muscle cone. The anterior portion consists of a hemisphere, from which a spike projects forward. Near the circumference are four slits, through which the muscles are drawn forward and impaled on the spike. They are then sutured together. Tenon's capsule is sutured over the muscle ends, and the conjunctival covering is closed. A conformer is placed in the conjunctival sac, which has a hole in the center to receive the tip of the spike. Iced compresses are used during the first twenty-four hours and pressure bandages for five days. A. G. Wilde.

Goldman, H. **Slit-lamp examination of the vitreous and the fundus.** Brit. J. Ophth. 33:242-247, April, 1949.

Inflammations, detachments, cysts, degenerations and tumors can usually be definitely diagnosed by fundus biomicroscopy, with the help of a fundus lens and the author's own prism for reducing the angle between the illuminating beam and the corneal microscope.

Orwyn H. Ellis.

Jaeger, A. **An addition to the nyctometer of Comberg.** Klin. Monatsbl. f. Augenh. 114:82-84, 1949.

In order to avoid variation in illumination of the Comberg nyctometer it is necessary to test the incandescent lamp more exactly than is possible by the use of a simple ampere or volt meter. The author describes a photometer for this purpose. (1 figure.) Max Hirschfelder.

Toennis, W. **Indications for surgical treatment of tumors in the sella turcica.** Klin. Monatsbl. f. Augenh. 114:1-18, 1949.

In a postgraduate lecture the author surveys tumors in the region of the sella turcica, which are about one fifth of all intracranial tumors. The pathologic findings associated with various tumors of this region (pituitary tumors, craniopharyngiomas, meningiomas, gliomas, aneurysm, epidermoids, arachnoiditis, tumors of the cranial base) are discussed briefly. (9 figures, references.)

Max Hirschfelder.

6

OCULAR MOTILITY

Abbate, Vincenzo. **A case of paresis of the elevator of the left upper lid and of the left external rectus, treated with injections of irradiated maternal blood.** Ann. di ottal. e clin. ocul. 74:369-374, May, 1948.

The nine-year-old patient received daily for eight days an injection of 4 cc. of her mother's blood which had been exposed for five minutes to ultraviolet radiation. Complete recovery ensued in about three weeks. The efficacy of irradiated maternal blood is ascribed not only to its physical properties but also to imponderable spiritual factors which transferred only from a mother to her child.

Harry K. Messenger.

Bruens, E. **Sutures used in resection for strabismus.** Klin. Monatsbl. f. Augenh. 114:62-69, 1949.

The author describes a modification of Blaskovics' two U-shaped sutures for his resection. (20 figures, references.)

Max Hirschfelder.

Bursaux, M. O. **Orthoptic treatment for strabismus.** Ann. d'ocul. 182:128-132, Feb., 1949.

The author compares the newer principles, methods and instruments used in orthoptic treatment with those of the older French masters such as Javal, Rémy and Landolt. Several French ophthalmologists studied orthoptics in the United States and Great Britain during and after the war. In their writings they have introduced the newer instruments, methods and principles to French ophthalmologists. An orthoptic clinic has been established in the Lariboissiere Hospital in Paris. The newer methods are but slightly improved adaptations of the fundamentals laid down largely by French ophthalmologists several generations ago. In many cases the results have been no better than those obtained with the older orthoptic methods.

Chas. A. Bahn.

Gartner, S., and Billet, E. **Progressive muscular dystrophy involving the extraocular muscles.** Arch. Ophth. 41:334-340, March, 1949.

A lesion of the nerve supply is so commonly the cause of palsy of an extraocular muscle that there is a great tendency to forget the rarer occurrence of a primary muscular disorder. Progressive muscular dystrophy was the cause of ptosis and divergent squint in a case presented. This case is the second in which histologic study of the extraocular muscles has been reported and the first in which involvement of the extraocular muscles has been demonstrated in a case of generalized progressive muscular dystrophy. The differentiation of primary muscular dystrophy and secondary muscular atrophy is discussed.

Ralph W. Danielson.

Gasteiger, H. **Some rarely performed muscle operations.** Klin. Monatsbl. f. Augenh. 114:49-54, 1949.

In four patients a high degree of paralytic strabismus was corrected by the method of Vogt. Three had extreme convergence. The medial rectus was completely tenotomized and severed from all its connections. Double-armed sutures were then laid through the superior and

through the inferior rectus and conducted laterally, subconjunctivally, and through the skin to a point lateral to the outer canthus. They pulled the eyeball straight and were removed after ten days. A similar method was used for a contraction of the superior rectus in the fourth patient. Muscle transplantation was done in three patients with paralytic strabismus. This method is of advantage when strong secondary contracture of the antagonist is lacking. (9 figures, references.)

Max Hirschfelder.

Kunz, E. **A method for exact dosage of strabismus surgery.** Klin. Monatsbl. f. Augenh. 114:55-62, 1949.

The effect of surgery in horizontal strabismus is mathematically analyzed. The rotation of the eye after unilateral surgery corresponds to the actual amount of advancement or recession multiplied by an undetermined factor. This factor is a fraction, the numerator of which is the elastic power of the antagonist, and the elastic powers of both muscles is the denominator. If equal amounts of recession and advancement are done on the two horizontal muscles at the same time, this factor can be disregarded. The article shows mathematically why this is the case. A schedule indicating the necessary amounts of recession and resection for all degrees of horizontal strabismus is displayed. (References.)

Max Hirschfelder.

Lienau, R., and Alvarez Montalván, E. **Bilateral congenital paralysis of the facial muscles and the lateral rotators.** Arch. de oft. de Buenos Aires 23:272-275, Oct., 1948.

A 20-year-old man was unable, from birth, to move his eyes outward, had bilateral facial paralysis, and a deformity of the feet. He had a moderate loss of visual acuity and normal fundi. The oculomotor apparatus was defective in associated lateral version. He could converge and at times force a bilateral diversion. There was only elementary fusion. (13 figures.)

Edward Saskin.

Loutfallah, M. **Surgery of the inferior oblique.** Ann. d'ocul. 182:81-121, Feb., 1949.

The muscles primarily and secondarily involved in paralyses of the vertical ocular rotation are discussed in detail. After a primary paralysis of the right superior rectus, a hyperfunction of the right inferior rectus and left inferior oblique may follow within a short time. Later a hyperfunction of the right inferior rectus and right inferior oblique with hypofunction of the left superior oblique may occur. The author presents the surgical anatomy and clinical physiology of the inferior oblique muscles at some length. Their proximity to the optic nerve and vorticose veins is important. Their torsional function is analysed. The indications for surgical weakening operations of the obliques include some forms of unilateral and bilateral hypophorias and tropias which may primarily involve the contralateral superior rectus; also disassociated vertical deviations with or without faulty insertion of the internal rectus. Methods for weakening include recession (White), myectomy with lid incision (Bonnet) and with conjunctival incision (Parker). Strengthening or reinforcing procedures include: resection (Berens), tucking (White), and advancement (Wheeler). Transplantation of the inferior oblique (Weiner) is seldom considered of value. Among the contraindications to inferior oblique surgery are slight and transient disassociated deviations, and faulty insertions. Operations and postoperative complications are discussed. Finally, an analysis of 38 operations performed by the author is presented in detail. The author prefers recessions and resections near the sclera to myectomy. (52 references.)

Chas. A. Bahn.

Piper, H. **The etiology of infantile ocular muscle disturbances.** Klin. Monatsbl. f. Augenh. 114:42-49, 1949.

The author describes nine children who had strabismus with secondary underaction of certain muscles. The first of three groups comprises cases of concomitant squint, in which lack of function during an important stage of development led to an underaction of a muscle. The second group involves supranuclear disturbances. In the third group isolated muscle paralysis with degenerative changes (shortening) lead to an underaction of the antagonist. The retraction syndrome belongs in this group. (13 figures, references.) Max Hirschfelder.

CONJUNCTIVA, CORNEA, SCLERA

Appelbaum, H. B., and Hale, A. S. **Aureomycin in dendritic keratitis.** J. Michigan St. M. Soc. 48:352, March, 1949.

The authors review the properties of aureomycin and its toxicity. A patient who had dendritic keratitis for over four years with frequent exacerbations was given two drops of aureomycin ophthalmic solution (0.5 percent) every two hours and was well in two days. There has been no recurrence. H. Weinberg.

Delaney, J. H. **Treatment of dendritic keratitis.** Pennsylvania M. J. 52:845-847, Sept. 25, 1949.

Dendritic keratitis is caused by a virus. Iodine therapy is still the best method of treatment. Streptomycin seems to inhibit the progress of the virus and aureomycin may well be an effective drug.
F. H. Haessler.

Houet, R., and Weekers, R. **Xerophthalmia of the newborn and hepatic insufficiency.** Arch. d'opht. 9:39-43, 1949.

The authors note that xerophthalmia in the newborn due to deficient intake of vitamin A is extremely rare, whereas xerophthalmia resulting from poor absorption of vitamin A due to various diseases, particularly of the intestinal tract, is more common. They describe two cases in which there was disturbance in the transformation of carotene into vitamin A in the liver. The first baby had a sudden attack of jaundice at the age of two months which recurred at intervals. At three months a corneal ulcer developed simultaneously with the onset of xerophthalmia. Following daily injections of 60,000 units of vitamin A, the xerophthalmia disappeared rapidly but the infant progressively lost weight and died. The lesion was a serious disturbance of the liver parenchyma. The second infant, premature at 7½ months, developed normally until the age of 3½ months when it developed bilateral corneal opacification with perforating ulcers of each eye. There appeared to be normal absorption of vitamin A and the diet had not been deficient. The child was placed on a daily dosage of 60,000 units of vitamin A and slowly improved, but the corneas healed with extensive scars.

The authors comment on the mechanism of vitamin A absorption and on the double role of the liver in vitamin A metabolism. It produces bile which emulsifies the fats, permitting absorption of vitamin A, and its parenchyma is concerned in the transformation of carotene into vitamin A. Phillips Thygeson.

Muller, P. **Mosaic degeneration of Bowman's membrane.** Ann d'ocul. 182:122-127, Feb., 1949.

This rare condition which Vogt has named "crocodile chagrain" is essentially a degeneration of Bowman's membrane which seems to be composed of round or polygonal cells. An illustrative case in a 51-year-old man is described. After slight injury to the left eye by a twig, hypopyon keratitis developed. Later, a transplantation operation was performed. The ex-

cised cornea showed breaks in Bowman's membrane, which were replaced by cicatricial tissue.   Chas. A. Bahn.

Paraipan, C. **Severe corneal ulcer cured by intraocular penicillin in 48 hours.** Ann. d'ocul. 182:133-134, Feb., 1949.

A 68-year-old man developed a severe corneal ulcer after injury. A solution of 10,000 units of penicillin to the cc. was injected into the anterior chamber and two subconjunctival injections of 10,000 units of penicillin were also made. The ultimate vision was 20/50.

Sená, J. A., and Cerboni, F. C. **Scleral excavations.** Arch. de oft. de Buenos Aires 23:313-325, Oct., 1948.

After a discussion of the history and pathology of such common afflictions of the sclera as senile hyaline plaques, inflammatory processes, and scleromalacia perforans a case is presented in which there were bilateral excavations of the sclerae, temporally, with typical senile hyaline plaques. (8 figures, references.)

Edward Saskin.

Trovati, E. **The bacterial flora of the conjunctiva in certain exanthematous diseases of infancy.** Ann. di ottal. e clin. ocul. 74:358-368, May, 1948.

The conjunctiva was not inflamed in scarlet fever and chickenpox; the conjunctival flora was normal in chickenpox, but in scarlet fever streptococci and staphylococci were isolated. Conjunctivitis is a usual accompaniment of measles, in which the flora is normal except for an increase in sarcinae, to which the conjunctivitis is attributed.

Harry K. Messenger.

Wenda, L. **The syndrome of blue sclerotics.** Arch. d'opht. 9:44-47, 1949.

The syndrome is a constitutional one with numerous complications in different organs and tissues of the body although the principal manifestation is blue scleras. The blue coloration of the scleras is not due to pigmentation but to the thinness of the structures which reflects a disturbance of the tissues of mesenchymal origin throughout the body. The disturbance is particularly marked in the bones, and repeated fractures are the rule. The ligaments are the next most seriously involved and dislocations of the joints and prolapses of various organs are common. Hemorrhages are frequent due to faulty connective tissue in the blood vessels. Visual disturbances due to cataract and deafness due to otosclerosis are common. Myopia with staphyloma has been reported. Wenda reports two cases, one a young girl of 16 years, the other a woman of 60, both with the classical syndrome. He notes, however, that whereas cases of the complete syndrome are rare, many instances of the incomplete syndrome have been reported. He states that women are more subject to the syndrome than men and urges that persons with this disease marry only individuals who are strong and vigorous.

UVEA, SYMPATHETIC DISEASE, AQUEOUS

Kapuscinski, W. J., Jr. **Pyretotherapy as a diagnostic provocative in uveitis.** Arch. d'opht. 9:27-30, 1949.

Kapuscinski uses typhoid vaccine intravenously in a technique devised by him which consists of a series of small doses increased gradually from .01 cc. to 1.0 cc. By this method he obtains a fever curve comparable to that of tertian malaria. He has found that in uveitis of tuberculous origin subjected to fever therapy there is usually an aggravation of the local eye lesion, an increase in the sedimentation rate, and sometimes a manifest oscillation of the daily tempera-

ture curve. In nontuberculous uveitis the fever therapy usually results in an acceleration of the sedimentation rate but does not change the daily temperature curve and affects the eye lesion favorably. In a series of 40 cases only four could be considered tuberculous. Fifteen cases are described in detail. The most frequent cause of uveitis is a streptococcal granuloma in a dead tooth or in the tonsils.

Phillips Thygeson.

Malbrán, J. L., and Rebay, C. A. **Rubeosis iridis and anterior glaucoma of Contino and Favaloro.** Arch. de oft. de Buenos Aires 23:276-291, Oct., 1948.

Rubeosis iridis is characerically seen in many diabetics on the anterior surface of the iris, from the root to the pupillary zone, as many radially arranged thin vessels that do not invade the pigmentary pupillary epithelium nor quite reach the angle of the anterior chamber, which description coincides with Salus' original observations. The ocular tension is often elevated. This syndrome may be more completely described as follows: painful glaucoma, deep anterior chamber, iris turbidity with new-vessel formation as described above, dilated pupil, with or without anterior chamber hemorrhage, and venous hyperemia. The authors point out that rubeosis may or may not exist with or without glaucoma and that the glaucoma may appear in patients without diabetes as well as in diabetics. Thirteen cases are described in detail and the important findings are tabulated. (4 figures, 1 table, 25 references.)

Edward Saskin.

Tower, P. **Traumatic choroiditis.** Arch. Ophth. 41:341-352, March, 1949.

Ten cases of so-called rupture of the choroid are reported. The etiology and pathology of these lesions are discussed. Discontinuity of the choroid following indirect injury to the eyeball is shown to

be due to necrotic changes of trophic character. A more precise terminology is proposed; "arciform traumatic choroiditis" is suggested for crescentic lesions and "diffuse traumatic choroiditis" for those of irregular outline.

GLAUCOMA AND OCULAR TENSION

Bloomfield, Sylvan. **The lability test: a new procedure for the diagnosis of chronic simple glaucoma.** New York State J. Med. 49:659-662, March 15, 1949.

The test combines the cold presser test of Hines and Brown and the jugular compression test described by Schoenberg. The patient lies flat on the table and one hand is immersed to the wrist in ice water. A blood pressure cuff around the neck is inflated to a pressure of 50 to 60 mm. Hg so that both jugular veins are compressed simultaneously. After one minute the tension is recorded. A rise of more than 9 mm. Hg (Schiøtz) above the ocular tension taken just before the patient immerses his hand in the ice water is a reliable aid in making a diagnosis of chronic simple glaucoma in that eye. This test compares very favorably with the other provocative tests now in use. The responses are greater and more easily recognized than those from the other tests in use. (4 figures.)

H. Weinberg.

Bonavolontà, Aldo. **Ophthalmoscopic examination with red-free light in glaucoma.** Ann. di ottal. e clin. ocul. 74:459-478, Aug., 1948.

In prodromal and incipient glaucoma slight fading of the macular yellow and diminution of the foveal reflex may be noticed, but nothing is found that might not be expected in the eyes of any elderly person. In more advanced cases the nerve fibers become attenuated and undergo fragmentation, and ultimately the pattern

of the nerve fiber layer is lost altogether and replaced by a marbled appearance, and likewise the foveal reflex becomes irregular in form, luminosity, and direction of movement, and may completely disappear. The macular yellow is also reduced or absent. Chronic simple and congestive glaucoma cannot be differentiated from each other by this means, but in the latter type the macula and the papillomacular bundle tend to be involved earlier and more extensively, whereas in chronic simple glaucoma the temporally situated nerve bundles may show the greater damage. The changes noted in glaucoma cannot be sharply distinguished from those found in atrophy of the optic nerve or macular degeneration due to other causes. (3 colored plates.)

Harry K. Messenger.

Raimondo, N. **Fuchs's heterochromia with glaucoma: pathogenetic considerations.** Ann di ottal. e clin. ocul. 74:423-435, July, 1948.

Raimondo reports two cases of Fuchs's heterochromia with glaucoma. The association of these two diseases is very rare. In one of his cases a bit of iris excised in trephining showed dystrophy of the stroma and rarefaction of pigment in the anterior limiting layer, conservation of the retinal pigment, thickening of the walls of the small vessels and capillaries, but no inflammatory changes. Raimondo's opinion is that both diseases are to be ascribed to congenital asymmetry in sympathetic innervation, which favors a vasomotor disequilibrium. (References.)

RETINA AND VITREOUS

Cremona, A. C., and Manzitti, E. **Biogenic treatment of pigmentary retinosis.** Arch. de oft. de Buenos Aires 23:309-312, Oct., 1948.

When parts of the body are isolated from their usual vascular and nervous connections they are said to develop "biogenic stimulants." Pieces of tissue of the

cornea, choroid, retina, cerebrum or placenta may be removed from the newly-dead and refrigerated. These may then be implanted beneath the skin or conjunctiva, or may be administered as an intramuscular injection. Intramuscular injections of placental extract were given to 33 patients with pigmentary retinosis with improvement in 13. (2 tables.)

Edward Saskin.

Eross, S., and Tarjan, G. **Retinal blood pressure in gravidic intoxications.** Orvosi Hetilap 26:406, Sept. 26, 1948.

In 41 gravid women with disturbances of the kidney or cardiovascular system, discordant values between the diastolic pressure of the central retinal artery and the brachial were found. Among these, 13 had eclampsia, in 3 intrauterine death of the fetus occurred, and one had myodegeneration of the heart, and lues. Concordant values were found in two pregnant women with essential hypertonia. In 50 healthy pregnant women they found no discordant values. The proportional rise of diastolic blood pressure in a retinal artery in severe nephropathia is a warning sign. In patients who had proportional diastolic pressure in the retinal artery the nephropathy did not become worse during pregnancy or delivery. (2 figures.)

Gyula Lugossy.

Fleischer, Eberhard. **Four new cases of Aguchi's disease.** Klin. Monatsbl. f. Augenh. 110:296-302, May-June, 1944.

All patients were males between 9 and 25 years old. There was pronounced night blindness since early childhood. Vision, visual fields and color sense were always normal. There were areas of grayish discoloration in the fundus, especially in the periphery. Mizuo's color-change was positive. After one hour in the dark the fundus looked normal, but changed to the original appearance after exposure to daylight. The dark adaptation was

very much delayed, but after three hours or more the values were normal. The change of the gray to normal fundus and the dark adaptation do not take place at the same rate but the cause of both is probably an abnormal breakdown and regeneration of the visual purple. The transmission is recessive and not sex-linked.

George Brown.

Friedenwald, J. S. **A new approach to some problems in retinal vascular disease.** Tr. Am. Acad. Ophth. pp. 73-87, Nov.-Dec., 1948.

A new staining method (Hotchkiss) which demonstrates fixed carbohydrate is applied to ocular tissues. Any cellular structure containing carbohydrate stains red. Structures taking the stain include conjunctival goblet cells, Bruch's and Descemet's membranes, lens capsule, the subepithelial basement membrane of the ciliary processes, the internal limiting membrane of the retina, and, to a lesser extent, the peripheral portion of the rods and cones. The entire retinal vascular tree has a subendothelial membrane which is readily demonstrable. It is broadest in the arterioles, and less in the venules, and thinnest in the capillaries. Its breadth and stability vary with the age of the individual rather than that of the vessel. Two capillary systems are demonstrable in the peripapillary zone of the retina. One is in the nerve fiber layer and has a rectangular configuration; the other is an irregular network in the inner nuclear layer. Only the latter persists peripherally. Capillary aneurysmal dilatations occur most frequently at the posterior pole and in the inner nuclear layer. They are consistently found in diabetic retinopathy and only rarely in other retinopathies. The development of the aneurysms is briefly discussed, and an analysis drawn between the endothelial changes of Kimmelstiel-Wilson intercapillary glomerulosclerosis.

A histochemical investigation of the cot-cotton-wool patches frequently seen in malignant hypertension is briefly discussed. They occur at the posterior pole and in the nerve fiber layer. These lesions were shown to be globular cytoid structures and to represent minute ischemic infarcts in terminal arteriolar bifurcations. Resorption is the usual course. The Hotchkiss staining procedure and its adaptation to ophthalmic uses is described in detail. Preparation of the reagents employed is outlined.

Grossmann, E. E., and Hitz, J. B. **Lipemia retinalis associated with essential hyperlipemia.** Arch. Ophth. 40: 570-573, Nov., 1948.

Since its first description, in 1880, about 60 cases of lipemia retinalis have been reported in the literature, and it is noteworthy that all have been in diabetic patients. The rare nondiabetic lipemia retinalis is associated with idiopathic hyperlipemia and is probably a familial anomaly of lipid metabolism that occurs in children. This case is the fifth recorded instance of lipemia retinalis in a nondiabetic person, and is probably the first in a nondiabetic adult.

<div align="right">Ralph W. Danielson.</div>

Guyton, J. S., and Reese, A. B. **Use of roentgen therapy for retinal diseases characterized by new-formed blood vessels (Eales' disease; retinitis proliferans): a preliminary report.** Arch. Ophth. 40: 389-412, Oct., 1948.

Intensive roentgen therapy to the posterior ocular segment was given in a series of patients with ocular diseases characterized by retinal and vitreous hemorrhages and by retinitis proliferans. Twenty-two eyes in 14 patients were treated. There was typical Eales' disease in 8 patients, atypical in 4, and diabetic retinitis proliferans in 2. The method de-vised by Martin and Reese for the treatment of retinoblastoma was used to avoid damage to the anterior ocular segment. A dose of 3,500 to 15,000 r was given each eye treated; doses of 6,000 r are probably optimal. There was moderate to complete collapse of new-formed vessels and variable regression of fibrosis. There has been only one recurrent hemorrhage since the treatment in the 8 cases of typical Eales' disease. In the patients with diabetic retinitis proliferans, hemorrhages have continued to appear.

Van Heuven, J. A. **Detachment of the retina following inflammation.** Tr. Ophth. Soc. U. Kingdom. 66:493-500, 1946.

A detachment of the retina about three months after an acute iritis showed a vitreous strand along the course of a vessel. No hole in the retina was visible for several days. Later a hole appeared and was cauterized. Beulah Cushman.

Hollenhorst, R. W., and Wagener, H. P. **The effect of rutin in the control of bleeding into the retina.** Am. J. M. Sc. 217:223-231, Feb., 1949.

The authors give a résumé of the work done on the treatment of retinal hemorrhages, especially those associated with increased fragility of the minute vessels of the skin, by such substances as citrin, hesperidin, and rutin. Rutin may decrease capillary fragility but it is not certain that increased fragility and permeability of the skin capillaries are accompanied by corresponding dysfunction of the retinal capillaries, especially in diabetic retinopathy. Some retinal hemorrhages may arise from a vitamin P deficiency. Evaluation of clinical improvement in the retina is most difficult. Superficial hemorrhages may be absorbed spontaneously in a short time, deeper ones may persist for a year or more, and all types frequently recur.

Rutin therapy in retinal complications of diabetes has been discouraging due to the deep location and the slow progress of the disease. In many other diseases the hemorrhages are more superficial and hence absorbed more rapidly. The value of rutin in retinal disease of diabetics is very doubtful.　　　　F. M. Crage.

Kinsey, V. E., and Zacharias, L. Retrolental fibroplasia. J.A.M.A. 139: 572-578, Feb. 26, 1949.

Since this disease was first associated with prematurity by Terry in 1942, there has been an increase in the number of cases reported which cannot be fully explained by the statement that the condition was formerly undiagnosed or missed, or that more premature infants survive now than before. Various factors were investigated which might have influenced this increase. The incidence of disease was higher in children born of multiparous women and in infants who remained in the nursery, incubator, and oxygen for longer than usual and also higher in the male. It might be of etiologic significance that the incidence was greatest during a time when there was increased use of vitamin in water-miscible form, and of iron. (14 tables.)
　　　　　　　　Bennett W. Muir.

Kreibig, W. Clinical demonstration of calcium deposits in retinoblastoma. Klin. Monatsbl. f. Augenh. 114:84-89, 1949.

Early necrosis of the gliomatous tissue often leads to calcium deposits in the intraocular part of the tumor. The author found these deposits in 16 of 20 eyes by histologic examination. No other intraocular tumor shows calcification, a fact which is of differential diagnostic significance. These calcium deposits form very soft shadows on the X-ray film. Positive findings remove all doubt. (7 figures, references.)
　　　　　　　　Max Hirschfelder.

Levitt, J. M. Occlusion of the cilioretinal artery. Arch. Ophth. 40:152-156, Aug., 1948.

Occlusion of the cilioretinal artery in a 19 year old woman is described. There was loss of central vision, a broad band of retinal edema between the optic nerve and macula and a large cecocentral scotoma. Intensive use of vasodilators was followed by almost complete recovery.　　　　John C. Long.

Lijó Pavía, J. Solar retinitis. Macular study with sodium light. Rev. oto-neuro-oftal. 23:71-78, Oct.-Dec., 1948.

In a previous paper the author established the fact that phototrauma of the eye results in a hole of the macula and central scotoma. Four cases of exposure to solar eclipse are presented now, each carefully studied with ordinary, red-free, and sodium light. The latter type of examination corroborated the findings with ordinary and red-free light, namely, mild optic neuritis, general retinal edema, alteration of the papillomacular fibers, marked central retinal edema, and a hole in the fovea. However, the pathologic picture was most readily appreciated in stereoretinography in yellow light. In all four cases visual acuity returned to normal in 20 to 68 days. (2 stereoretinographs.)　　　　Edward Saskin.

Lijó Pavía, J., and Cabrera, M. Vitreous humor substitution. Rev. oto-neuro-oftal. 24:13-17, Jan.-Feb., 1949.

The authors' surgical procedure is performed under pentothal and consists of an equatorial scleral incision through which 1.50 cc. of vitreous is removed by syringe and an 18 gauge needle. The syringe is then removed but the needle is left in situ, and 2 cc. of clear donor vitreous from an enucleated eye in another syringe is injected into the vitreous cavity through the same needle. The

scleral incision is then sutured. In an only eye with turbid vitreous visual acuity improved from perception of shadows to 20/200. Edward Saskin.

Linde, L. **Prophylactic surgery for potential retinal detachment.** Klin. Monatsbl. f. Augenh. 113:140-142, 1948.

The case histories of five patients in whom a prophylactic fixation of the retina was necessary are presented. The author recommends such surgery in all cases of retinal tears, whether detachment has occurred or not. It is imperative to investigate such an eye carefully for new tears even after seemingly successful surgery and the other eye as well. Prophylactic diathermy surgery also has a place in eyes that are inclined to retinal detachment. In a patient with Marfan's syndrome such prophylactic fixation was done and no detachment followed surgery for a dislocated lens. This type of surgery is harmless and obviates perforating procedures. Max Hirschfelder.

Loewenstein, A., Michaelson, J. C., and Hill, J. **Retinal vasculitis of the young: a pathological report.** Tr. Ophth. Soc. U. Kingdom 66:211-230, 1946.

The author reports the pathologic findings in two eyes with retinal vasculitis. The eyes had been enucleated in young people because of glaucoma. Histologic studies revealed numerous retinal hemorrhages, ectasia of the retinal vessels and venous stasis. Hemorrhages were present in the thickened vessel walls. There was extensive granulomatous infiltration of many venous walls. The choroid was normal. Numerous sections were stained with Ziehl-Neelsen's stain but no acid fast bacilli were found. Animal experiments suggest the presence of an infective agent in the retina. It is suggested that the use of retinal tissue for biological experiment may be a fruitful approach to the problem of causation. (19 figures.) Beulah Cushman.

Maggiore, L. **Histologic changes in retinal edema.** Ann. d'ocul. 181:681-691, Nov., 1949.

The most important factors in injury to the retina caused by edema are the intensity and duration of the edematous infiltration, its location, the coexistence of hemorrhage, and the coexistence of toxic or infectious disease. Variations in the degree of edema determine the degree of structural damage to the retina and whether vision is temporarily or permanently injured. Edematous infiltration of the fibers of Henle's layer may cause a hole in the fovea, an important factor in some cases of retinal detachment. The disposition of the fibers of Henle's layer in the macular region explains how intense edema can pull apart these fibers without causing rupture at the periphery of the fovea, whereas at the center, where the fibers are short and lie perpendicularly, stretching will tear them and produce a hole. If the edema is limited to the internal layers of the retina the hole will be superficial and the detachment intraretinal; if a massive edema infiltrates even the visual cells, the hole will penetrate the foveal retina throughout its thickness and will be complete, that is, a true retinal detachment. Chas. A. Bahn.

Malatesta, C. **Two cases of pigmentation of the disc after retinal detachment operation.** Boll. d'ocul. 32:722-733, Nov., 1948.

Two men, aged 49 and 57 years, had extensive dispersed pigmentation of the retina and the optic discs after diathermy coagulation for retinal detachment. The pigmentation appeared a few days after the operation and disappeared gradually in a month. (2 colored drawings.) K. W. Ascher.

Malbran, and Montalvan. **Pseudoforamina of the macula in disinsertions of the ora serrata.** Arch. de oft. de Buenos Aires 23:252-258, Sept., 1948.

There is little in the literature on the association of dialysis of the ora serrata with a pseudoforamen of the macula which was first described by Vogt in 1936, and is of interest in diagnosis, prognosis and therapy. Six cases are reported.

This is one of the forms of cystic degeneration of the macula. There is a reddish discoloration at the macula of variable size. The edges are clear-cut and surrounded by pale and edematous retina. The macular region is raised as if by a single or multiple tense vesicle of variable transparency. There is a foveal reflex because the internal limiting membrane is preserved. Fine striations extend outward from the macula. Differentiation from a traumatic or spontaneous hole at the macula is at times difficult. A. G. Wilde.

Marín Amat, M. **Spasm of a cilio-retinal vessel, and of the superior branch of the central retinal artery.** Arch. Soc. oftal. hispano-am. 9:91-93, Jan., 1949.

A woman had an ophthalmoscopically visible spasm of a cilioretinal artery with a total loss of the lower half of the visual field. After treatment with vasodilators vision was restored, and only slight pallor of the disc, and a slight constriction of the upper retinal vessels remained. Treatment must not be abandoned too early, persistence frequently leads to surprizing results. (3 visual fields.) Ray K. Daily.

Mariotti, Lorenzo. **Intravenous procaine and para-aminobenzoic acid in the treatment of thrombosis of the central retinal vein.** Ann. di ottal. e clin. ocul. 74:350-357, May, 1948.

Mariotti reports three cases of thrombosis of the main branch of the central retinal vein, and nine of thrombosis of a branch of the vein, in which 20 to 180 mg. of procaine were given in 2 to 18 intravenous injections of a 1- or 2-percent solution at intervals of a day or more. This therapy was ineffective in thrombosis of the trunk, but in the other cases the results were encouraging. The systemic systolic pressure, the retinal arterial pressure, and the ocular tension were always reduced. The efficacy of procaine in dislodging the thrombus seems to be due in great part to its vasodilator action. Presentation of the results obtained with para-aminobenzoic acid is reserved for another paper. Harry K. Messenger.

Moreu, Angel. **Observations on the pathogenesis and treatment of diabetic retinopathy.** Arch. Soc. oftal. hispano-am. 9:139-146, Feb., 1949.

The physiologic action of hyalouronic acid and hyalouronidase is reviewed. The development of diabetic retinopathy is attributed to variations in the sugar metabolism, caused by injudicious use of insulin. Hypoglycemia stimulates the production of hyalouronidase which destroys hyalouronic acid, and increased fragility of the vessel walls and hemorrhages follow. In the hyperglycemic phase an excess of hyalouronic acid stimulates the organization and proliferation of connective tissue. It is urged that insulin be used with great caution and that more attention be paid to capillary fragility. Agents that improve cellular respiration such as heparin are indicated.

Ray K. Daily.

Oravisto, T. **The ocular symptoms of arterial hypertension.** Ophthalmologica 117:161-168, March, 1949.

The author reports his examination of 70 patients under 50 years of age with pure essential hypertension and as little sclerosis as possible. The classification of hypertensive cardiovascular disease according to Keith-Wagener is recom-

mended as a basis for cooperation between the internist and ophthalmologist.

Peter C. Kronfeld.

Reese, A., and Blodi, F. **Retrolental fibroplasia.** Klin. Monatsbl. f. Augenh. 114:18-24, 1949.

Three groups of retrolental fibroplasia are discussed. Dysplasia of the retina is a bilateral malformation with persistence of the primary vitreous and lack of formation of the secondary vitreous. It is often associated with other malformations of the brain and the vascular system. Hyperplastic primary vitreous is usually unilateral and characterized by hyperplasia in the central retrolental region. True retrolental fibroplasia forms a third group which has increased in frequency during the past few years. Persistence of the primary vitreous leads to a dense grayish tissue formation behind the lens with its densest parts near the equator of the lens. The lens itself stays clear. Detachment of the retina is found in the final stages. The disease is always bilateral and prevalent among premature children. The theories of its etiology and the therapy are discussed. (References.)

Max Hirschfelder.

Schiff-Werthheimer, S., Jonquères, J., and Jarry, C. **Retinal detachment of young myopes.** Ann. d'ocul. 182:13-23, Jan., 1949.

The prognosis and symptomatology of 49 patients under 30 years of age with an average myopia of 12D are described. The prognosis is worse in the younger group. After operation, one third had a corrected vision of 0.1 or more and almost one half had no vision. Multiple tears are more frequent than in unselected cases and bilateral detachment is more frequent in the young.

Tirelli, G. **A case of macular hole following rapid lowering of atmospheric pressure.** Rassegna ital. d'ottal. 17:353-356, Nov.-Dec., 1948.

A 30-year-old man, a former aviator and Alpinist, suffered an epistaxis, rapidly followed by a sudden loss of vision while mountain climbing at an altitude of 4,000 meters and after passing through a severe storm. The ophthalmoscope disclosed a round hemorrhage at the macula of the left eye. In all other respects the eyes were healthy. Two months later, the hemorrhage was absorbed leaving a clear-cut, round hole, one half the disc diameter in size, exactly at the macula. The author assumes that the diminished atmospheric pressure and the low barometric pressure accompanying the storm and increased capillary fragility from severe fatigue caused the hemorrhage.

Eugene M. Blake.

Unsworth, A. C. **Retrolental fibroplasia.** Arch. Ophth. 40:341-346, Sept., 1948.

In observing the eyes of premature infants from birth, the author rarely saw remnants of the hyaloid artery but they appeared shortly. Of 30 premature infants none was born with a retrolental membrane. In two infants that he saw shortly after birth without evidence of ocular abnormality, retrolental fibroplasia has since developed. He believes that retrolental fibroplasia as it is usually known is not congenital. In one case, at least, the mechanism of its formation was seen to be leakage of blood from the retinal vessels into the vitreous, followed by vascularization of the hemorrhage in the vitreous from the retinal vessels. Remnants of the hyaloid artery were not persistent in any of these cases and certainly played no part in the formation of the angioplasia of the vitreous. He feels sure that this condition, if untreated, will become a typical retrolental fibroplasia by spreading over the posterior surface of the lens. This formation seems to be akin

to the formation of granulation tissue elsewhere in the body, to retinitis proliferans or to the syndrome of von Hippel's angiomatosis. The anemia of prematurity in itself may be a factor in the causation of retrolental fibroplasia. There seem to be two main types. The first develops from the proliferation of vascular tissue from the retinal vessels of the posterior portion of the fundus into abnormal vitreous. The second is the result of failure of development or condensation of the secondary vitreous at the anterior periphery, with proliferation into it of retinal vessels from the unattached peripheral portion of the retina.

Ralph W. Danielson.

Verhoeff, F. H. **Successful diathermy treatment of recurring retinal hemorrhage and retinitis proliferans.** Arch. Ophth. 40: 239-244, Sept., 1948.

Recurring retinal hemorrhage in the young is frequently associated with ophthalmoscopically recognizable periphlebitis. Usually there is a cutaneous reaction to tuberculin, and nodular foci of epithelioid cells along the veins have been observed. Histologically there is strong evidence that tuberculosis is the cause. The hemorrhage evidently results from engorgement of capillaries and small veins and when it is severe and persistent, new vessels are formed, which may extend into the vitreous. Hemorrhage into the vitreous usually occurs, and the blood becomes organized, thus producing typical retinitis proliferans. The author reports in detail the successful use of diathermy in such a case.

Ralph W. Danielson.

Wagner, E. **A late form of familial amaurotic idiocy in a brother and sister.** Klin. Monatsbl. f. Augenh. 114:37-42, 1949.

There was no sign of retinitis pigmen-tosa. The brother showed a secondary optic atrophy, concentric contraction of the field and colorblindness. Neurologic investigation by means of X ray, encephalograms and biopsy revealed increased intracranial pressure and the damage to the ganglion cells of the cortex characteristic of familial amaurotic idiocy. The sister who had a normal mind had a nystagmus, was colorblind and had a pituitary form of adiposity.

NEURO-OPHTHALMOLOGY

Becker, F. Y. **Herpes zoster ophthalmicus: results of treatment with transfusions of convalescent blood.** Arch. Derm. and Syph. 58:265-275, Sept., 1948.

The author reports six cases of herpes zoster ophthalmicus treated successfully by the method of Gunderson, who gives 250 to 450 cc. of convalescent blood intravenously early in the disease, preferably before involvement of the eye. Herpes zoster is probably caused by a virus because recurrences are unusual, inclusion bodies are present in the vesicles, and there are antibodies in the serum of convalescent patients. However, because the agglutinins do not appear until the third week, convalescent serum should be given early. After transfusion, the temperature becomes normal, pain is alleviated, the edema and infiltration are decreased, the patient is less toxic, and the ophthalmic lesions begin to heal.

Bridges, T. J., Pool, J. L., and Riley, C. M. **Central autonomic dysfunction with defective lacrimation. II. Preliminary report of effect of neurosurgery in one case.** Pediatrics 3:479-481, April, 1949.

A division of the tentorium on the right side was performed on a 4-year-old boy

with defective lacrimation and central autonomic dysfunction. Lacrimation made its appearance on the sixth postoperative day and has persisted. The lability of blood pressure and the abnormal reactions disappeared immediately, only to return after a period of three weeks.

I. E. Gaynon.

Fonte Barcena, A., and Manzilli, E. **Ophthalmoplegic migraine.** Arch. de oft. de Buenos Aires 23:233-239, Sept., 1948.

Typical ophthalmoplegic migraine that occurred in a 51-year-old woman is described and our meager knowledge of the syndrome is discussed.   A. G. Wilde.

Freymann, M. W., and Bang, F. B. **Human conjunctivitis due to Newcastle virus in the U.S.A.** Bull. Johns Hopkins Hosp. 84:409-413, May, 1949.

Three laboratory workers developed conjunctivitis with preauricular adenitis due to the virus of Newcastle disease in chickens. Virus was isolated in two of the eyes. The course was brief, without complication, and lasted three to five days.   I. E. Gaynon.

Guthkelch, A. N. **Extradural hemorrhage as a cause of cortical blindness,** J. Neurosurg. 6:180-182, March, 1949.

A case of almost total cortical blindness due to bilateral occipital extradural hematoma is recorded.

Miss L. K., 67 years old, struck the back of her head. She was drowsy and irritable. Xrays revealed a fissured fracture. After four days her conscious level improved, but she complained of blindness. Ten days later she was garrulous, euphoric and devoid of insight. The discs showed acute papilledema with hemorrhages, but no exudate and the pupils were normal. A diagnosis of bilateral occipital subdural hematoma was made. At operation a huge black clot was re-

moved from the extradural space. Two days later the visual acuity improved and on the fourth day she could read a newspaper comfortably. When last seen one year later her health was excellent and she was able to do fine work as well as ever. Her visual fields remained full and the optic discs had returned to normal.

Theodore M. Shapira.

Jensen, Jens. **A case of herpes zoster ophthalmicus complicated with neuroretinitis.** Acta opth. 26:551-558, 1948.

Herpes zoster ophthalmicus occurred in a 9-year-old girl after she was exposed to varicella during an epidemic. The disease was complicated by optic neuritis, retinitis, internal ophthalmoplegia, optic atrophy and macular changes. The literature on similar complications of herpes zoster is reviewed.   Ray K. Paufique, Mayoux, Hugonnier, and Aubert. **Parinaud's syndrome associated with vertigo.** Ann. d'ocul. 182:1-12, Jan., 1949.

A man, aged 49 years, noted transient diplopia for about three hours. Subsequently he developed a bilateral paralysis of elevation and convergence with vertigo. Parinaud's syndrome is apparently due to a lesion in the posterior white commissure of the pons. The vertigo was believed due to a lesion in the vestibular nucleus, probably near the nuclei of Bechterew and Deiter. The cause was

probably a vascular disturbance. The blood supply of the pons includes rubo-pyramidal, oculo-nuclear and lateral sulcus arteries.   Chas. A. Bahn.

Riley, C. M., Day, R. L., Greeley, D. M., and Langford, W. S. **Central autonomic dysfunction with defective lacrimation. I. Report of five cases.** Pediatrics 3:468-478, April, 1949.

A syndrome consisting of diminished to absent lacrimation, hypertension, skin blotching, drooling, cold hands, cyclic vomiting, mental retardation and hyporeflexia in children is presented. The findings seem best interpreted as a central, possibly congenital, disturbance of autonomic function. (1 table.)

I. E. Gaynon.

Sitler, R., Cremona, A., and Manzitti, E. **Myasthenia of visual type.** Arch. de oft. de Buenos Aires 23:226-232, Sept., 1948.

A four-year-old boy had equal and progressive bilateral ptosis, since he was two and a half years old. He was able to open the eyes during the early morning hours, but this power decreased during the day. There was also an almost complete immobility of the eyes. The excursion of the gaze was about two millimeters. No other symptoms were demonstrable. The distinguishing feature of this disorder is a rapidly increasing fatigability of the involved muscles, which improves after variable periods of rest. It is necessary to differentiate myasthenia from congenital ophthalmoplegia and the chronic external type, which is progressive. A diagnostic aid is the dramatic improvement or even temporary disappearance of symptoms after prostigmin.   A. G. Wilde.

Spadavecchia, Vitangelo. **Nasociliary neuritis.** Ann. di ottal. e clin. ocul. 74: 321-338, May, 1948, 436-455, July, 1948.

The first installment of this monograph

was abstrated in Am. J. Ophth., Sept., 1942.

Four types of nasociliary neuritis are recognized: the simple irritative, the irritative-inflammatory, the atrophic, and the postinflammatory atrophic-degenerative. Our knowledge of the pathogenesis of this disease is much limited by the absence of histopathologic material and by our ignorance of the reciprocal influence between the central and the autonomic nerve fibers in the nasociliary region. Neuritic pain, photophobia and blepharospasm are referable to cerebrospinal elements, whereas vasomotor and secretory disturbances point to autonomic involvement. The symptoms are so typical that the diagnosis is easy, but in making a differential diagnosis it is necessary to eliminate neurosis, simple nasociliary irritation, lesions of the fifth cranial nerve, certain types of headache, and acute glaucoma. Symptomatic treatment of pain is indicated, and cocainization and adrenalization of the nasal fossa are of value. Intranasal foci or spurs causing irritation should be treated surgically, and in severe cases the injection of alcohol in the region of the nasociliary nerve is advised. (References.)

EYEBALL, ORBIT, SINUSES

Belmonte-González, Manuel. **Hydatid cyst of the orbit.** Arch. Soc. oftal. hispano-am. 9:49-59, Jan., 1949.

A diagnosis of a hydatid cyst of the orbit was made in a woman 24 years old, with a rapid onset of exophthalmos, diplopia, displacement of the eyeball downwards, choked disc, and loss of vision and the absence of rhinologic and roentgenologic signs of paranasal sinusitis. The cyst was exposed through a canthotomy, punctured, evacuated and filled for a few minutes with a 1-percent solution

of formalin (its deep location precluded complete extirpation) and the wound was sutured and drained. The patient recovered with recession of the choked disc, restoration of vision but with restriction of lateral rotation, and diplopia. (3 figures.) Ray K. Daily.

Buesa, Lorente. **A case of thrombophlebitis of the cavernous sinus.** Arch. Soc. oftal. hispano-am. 9:34-48, Jan., 1949.

An acute fulminating case of thrombosis of the right cavernous sinus is reported in a man, 46 years old. The infection originated in the last right lower molar tooth and advanced through the inferior dental veins. It was complicated by an orbital abscess which drained spontaneously at the inner canthus. In addition to the classical symptoms there was myosis of the right eye which is attributed to a venous stasis in the iris and a paresis of the sympathetic fibers in the first branch of the trigeminal. The patient recovered under treatment with penicillin and sulfa drugs. Ray K. Daily.

Hughes, W. L. **Metallic implants and integrated artificial eyes.** Plast. and Reconstruct. Surg. 4:175-177, March, 1949.

The author has originated four types of Vitallium implants for use with integrated artificial eyes. They have a flat face with depression anteriorly to receive the peg on the posterior surface of the eye. No reaction has been noted from these implants. Few extrusions have occurred, and in them the usual buried implant was used. Alston Callahan.

Larsson, H., Lindblom, K., and Stenström, S. **Clinical and roentgenological view regarding the localization of foreign bodies in the orbit.** Acta ophth. 26:557-580, 1948.

This symposium consists of 3 papers. Stenström discusses the relation of varia-tions in the size and shape of the eye to the accuracy of roentgenographic localization. He reports graphically the data of measurements of the vertical diameter of the eyeball in 1,000 cases, and of the horizontal diameter in 766. The vertical diameter was determined by Rushton's method, and the horizontal measured with Berg's appliance. The charted data show that the size and form of the eyeball are subject to such marked variations that in cases requiring precise localization the determination of the length and equatorial diameter of the eyeball is indispensable.

Lindblom describes his method of bitangential roentgenographic localization without determination of the size of the eyeball. It consists in getting a shadow of the cornea on the film by surrounding it with air; the upper lid is elevated with a spring, and the lower lid fastened down with adhesive tape. The degree of magnification of the cornea in the radiographs is calculated from the focal film and focal eye distances. Outlines of normal eyeballs corresponding to the degree of magnification engraved on transparent film are placed on the radiograph and the distance of the foreign body from the coronal, sagittal, and horizontal midplanes of the eyeball measured. The relation of the foreign body to the cornea and sclera can be seen on the film.

Larsson's method of localization includes concurrent determination of the size of the eyeball. Various methods for determining the size of the eyeball are discussed, and preference expressed for a modification of Rushton's method. The modification consists in moving the eyeball forward to the X-ray beam, instead of moving the beam to the posterior pole of the eye. The shadow of the cornea is visualized on the same film which indicates the posterior pole of the eye with a dark streak; the axial length of the eye-

ball can thus be measured on the film. The apparatus and technique are described in detail. (12 figures.)   Ray K. Daily.

Lisch, K. **Familial occurrence of spontaneous pulsating exophthalmous.** Ophthalmologica 177:180-185, March, 1949.

Spontaneous (nontraumatic) pulsating exophthalmos was observed in a man, 23 years of age, and his sister, 45. In the latter the disease occurred bilaterally. The father of the two patients developed sudden unilateral proptosis at the age of 47 and died of apoplexy two years later. A hereditary predisposition to arterial rupture is assumed.

Peter C. Kronfeld.

Pallarés, J. **A case of sarcoma of the orbit, with diagnostic puncture and microscopic study of the fluid.** Arch. Soc. oftal. hispano-am. 9:60-67, Jan., 1949.

The diagnosis of intraorbital sarcoma in an infant, 29 months old, was made from a cytologic study of material aspirated through a puncture of the tumor. After aspirating the fluid with a syringe, a diathermy current was passed through the needle for 15 seconds.

Ray K. Daily.

Pallestrini, Ernesto. **Blepharospasm and palpebral tic from sinusitis.** Riv. oto-neuro-oftal., 23:275-283, July-Aug., 1948.

A woman, 35 years of age, had unilateral fronto-maxillary sinusitis with homolateral blepharospasm. The spasm disappeared after the sinuses were clear. Three years later with recurrence of sinusitis there was bilateral blepharospasm together with spasm of the frontalis muscle and lacrimation under strong light. After radical surgical operation on the sinuses, the spasmodic condition disappeared permanently. The mucous membrane of the sinuses was found to be thickened with pseudomixomatous degeneration.   Melchiore Lombardo.

Waugh, D. B. **Ocular prosthesis, with special reference to the conjunctival sac.** M. J. Australia 1:311-313, March 5, 1949.

It is important that the conjunctival slack present in both fornices be preserved following enucleation in order to preserve the palpebral fold and the facial characteristics of the person involved. An acrylic splint made from the impression of the closed eye which is to be excised should be slipped under the lid following surgery in order to prevent the upper lid from being drawn inward.

I. E. Gaynon.

EYELIDS, LACRIMAL APPARATUS

Bassenge, W. **Irrigation of the tearsac with penicillin in dacryocystitis.** Klin. Monatsbl. f. Augenh. 113:363-366, 1948.

After a series of irrigations with penicillin solution (50 Oxford units per cc.) in 20 patients, an improvement in the bacterial flora of the sac was the rule and in some cases the bacterial findings became negative. Whenever there was a patent sack originally or after probing, penicillin seemed effective. Patients with closed tearducts cannot be cured by this treatment. However, preparatory penicillin irrigation has a favorable influence on subsequent surgery. Dacryorhinocystostomy is recommended. (References.)   Max Hirschfelder.

Berke, R. N. **Motais-Parinaud type of operation for ptosis.** Arch. Ophth. 41:324-333, March, 1949.

Utilization of the superior rectus muscle to correct ptosis in 35 cases of congenital ptosis gave an excellent result in 4 cases, a good result in 14, a fair result in 8, and no improvement in 9. In 16 of 22 cases in which the Motais-Shoemaker-Kirby technic was used, and in 10 of 13 cases in which the Parinaud-Young-Dickey procedure was employed, im-

provement followed. Utilization of the superior rectus to correct ptosis induced weakness of that muscle in 26 of 35 cases. Lagophthalmos in sleep was present in most of the cases of corrected ptosis, but no evidence of corneal ulceration occurred. This type of procedure should be used only for ptosis with complete paralysis of the levator palpebrae and integrity of the superior rectus muscle function.

Ralph W. Danielson.

Chabat, H. **Operation for trachomatous trichiasis by the conjunctival route.** Arch. d'opht. 9:48-51, 1949.

Chabat favors the conjunctival route for the correction of trichiasis because 1, it does not mutilate the tarsus, 2, it leaves no externally visible cicatrix, and 3, it requires no assistant, thanks to the use of a simple lid everter with two hooks for the attachment of sutures. A conjunctival incision is made 0.5 cm. from the free border of the lid, extending through the tarsus only, and dividing the tarsus into two portions. The marginal portion of the tarsus is dissected free from the overlying muscle and skin up to the bulbs of the cilia, while the remaining portion is also dissected free, well into the angles but not into the tendon of the levator. Four mattress sutures are then placed in such a way as to bring the cut border of the tarsus into the sulcus formed between the marginal tarsal leaf and the overlying skin, the sutures presenting at the lid margin. This everts the cilia, producing an ectropion which lasts for several weeks. The author comments on the relative freedom from recurrences.

Phillips Thygeson.

Ferraris de Gaspare, P. **Congenital fistulas of the lacrimal sac.** Boll. d'ocul. 27:739-745, Nov., 1948.

Two patients with congenital fistulas of the lacrimal sac were observed. Histologic examination of one showed a fistula lined by epithelial cells similar to those of the lacrimal ducts. (References.)

K. W. Ascher.

Lagrot, Félix. **Dermo-epidermic free grafts of the lids.** Ann. d'ocul. 182:32-51, Jan., 1949.

The indications for this type of graft include cicatricial retractions, entropionlagophthalmus, primary gangrene, injuries of the lids, and lid conditions secondary to facial or orbital disease. The author prefers general anesthesia. After a horizontal lid incision with dissection, four sutures are placed into the upper and lower margins, and held with artery forceps. A compress of vaseline gauze is used to form a temporary mold to cover the lid wound. A graft is taken from the inner side of the upper arm and placed on the mold. The upper and lower lid sutures are used to close the wound. In 17 operations there was no failure. Chas. A. Bahn.

Marcks, K. M. **Repair of defects produced by excision of tumors in the eye region.** Plast. and Reconstruct. Surg. 4: 178-187, March, 1949.

The complete removal of the tumor is preferred to the biopsy of a small amount of tissue. Primary repair should be instituted in all surgical excisions. Six varied cases are presented by means of brief histories, description of surgical procedure, and 26 photographs but no drawings. Secondary repair is performed after it is certain there will be no recurrence or extension of the initial lesion.

Alston Callahan.

Moulié, H. B., and Baron, H. G. **Dacryocystorhinostomy in the young.** Arch. de oft. de Buenos Aires 23:298-301, Oct., 1948.

Sac extirpation should not be performed in the young because a life time of annoyance follows. Dacryocystorhinos-

tomy may be done in the young in chronic dacryocystitis or narrowing of the terminal portion of the nasolacrymal canal, and is almost always successful.

Edward Saskin.

Nordenson, J. W. **Jean-Louis Petit and the mechanism of lacrimal drainage.** Arch. d'opht. 9:5-8, 1949.

Nordenson reviews the studies of the celebrated French surgeon, Jean-Louis Petit, which were made in 1734 and published under the title of "Memoire on Lacrimal Fistula." Petit attributed the flow of tears into the nose to a siphon action of the lacrimal passages, and to action of the lids in closing the conjunctival sac and pressing fluid into the canaliculi. These theories need reëxamination in view of the data obtained from dacryocystorhinostomy. Neither complete incision of the canaliculus nor removal of the lacrimal sac interferes with lacrimal drainage. Petit's lid closure theory would explain the tear flow in such cases. After a review of the literature and a consideration of his own observations, Nordenson concludes that Petit's siphonal theory can only be accepted in rare cases in which the transport of tears occurs in spite of paralysis of the facial nerve, but the theory of lid closure has been unjustifiably disputed. If it is correct, dacryocystorhinostomy is indicated when the canaliculi have been slit.

Phillips Thygeson.

Pereyra, C. C. A., and Riva, A. **Conjunctivitis and palpebral itching.** Arch. de oft. de Buenos Aires 23:259-271, Oct., 1948.

Palpebral itching is a definite entity, and may exist alone as a result of mechanical, chemical, or medicinal irritation, chronic conjunctivitis, epiphora, refractive errors, allergy, or from neuro- or psychogenic factors. If the complaint be associated with a systemic condition such as arthritis, diabetes, or endocrine dys-

crasia, the latter should be given treatment as the possible initiating agency in addition to the therapy for the relief of the itching. The authors sometimes use the antihistaminic drugs.

Edward Saskin.

Shuttleworth, F. N. **An advocacy of external dacryo-cystorhinostomy.** Brit. J. Ophth. 33:183-187, March, 1949.

British ophthalmologists have not generally adopted the Toti operation and the author presents the results in 60 cases with a recommendation that the operation be more generally done.

Morris Kaplan.

16

TUMORS

Arjona, J. **Sturge-Weber syndrome with ocular melanosis.** Arch. Soc. oftal. hispano-am. 8:1207-1218, Dec., 1948.

A boy, 13 years old, had epilepsy, numerous angiomas, buphthalmos in the left eye, chronic glaucoma in the right and blue scleras. The tension in both eyes was normal, although the anatomic changes indicated that it must have been high at some time. He had a small sella turcica, and calcification about the occipital lobes. Gradual improvement in the epileptic seizures is ascribed to a diminution in the meningeal angiomas. Involution of the angiomas of the choroid probably accounts for the normal tension. The blue scleras caused by melanosis are attributed to an abnormal activity of melanoblasts because of excessive choroidal vascularization. The literature on the pathogenesis of Sturge-Weber disease is reviewed, and it is suggested that melanosis of the eyeball may be a fourth symptom in the syndrome of angiomas, ocular and cerebral disturbances. (5 figures.)

Ray K. Daily.

Bloch, F. J. **Retinal tumor associated with neurofibromatosis (von Reckling-**

hausen's disease). Arch. Ophth. 40:433-437, Oct., 1948.

A classification of the ocular complications of neurofibromatosis is given. The author reports a retinal tumor in a 60-year-old man with neurofibromas of the trunk and extremities. The tumor was ophthalmoscopically identical with tumors seen in tuberous sclerosis. In nine years of observation the fundus picture has not changed.   John C. Long.

Costi, C. Multiple teratoid dermoids. Arch. Soc. oftal. hispano-am. 9:28-33, Jan., 1949.

An unusual case of multiple teratoid dermoids in the lids and on both eyeballs of a child, 20 months old, is reported. The diagnosis was made by biopsy. (4 figures.)   Ray K. Daily.

Moehle, W. Myxosarcoma of the eyelid. Arch. Ophth. 41:317-323, March, 1949.

This myxosarcoma of the eyelid apparently resulted from trauma. There was no evidence of abnormality before the accident or in the next two weeks; then a lesion appeared on the upper lid and enlarged rapidly. The growth resembled a hematoma but changed within two months to a firm, unyielding mass. Partial resection of the tumor and radiation therapy were employed. The eye was removed two years after this operation. Biopsy specimens from the surrounding areas showed no residual tumor, and no evidence of metastasis has been found. The boy is in good health; he has developed normally and presents no defects other than the loss of one eye. At present, nearly seven years after the appearance of the initial lesion, there is no reason to suspect a recurrence of the malignant growth.   Ralph W. Danielson.

Nuti, F. An atypical case of Sturge-Weber's syndrome. Boll. d'ocul. 27:734-738, Nov., 1948.

A 20-day-old girl had a nevus flammeus, resembling a telangiectatic angioma, on the right cheek and eyelids, congestive glaucoma of the right eye and slight enlargement of the right cornea. Treatment with a 2-percent pilocarpine solution seemed satisfactory, but at the age of two years a typical excavation of the right disc was observed. The angioma gradually disappeared.   K. W. Ascher.

Paufique, Offret, G., and Vouters. Peripheral glioma of the orbit. A clinicopathologic study. Arch. d'opht. 9:9-26, 1949.

The authors deplore the confusion existing in the literature and in the current textbooks on orbital tumors, particularly the tumors of the optic nerve which are known as gliomas, neurinomas, or schwannomas. They point out the close relationship existing between the solitary nerve tumor and von Recklinghausen's disease. In the latter the diagnosis is facilitated by the associated lesions while in the isolated neurinoma diagnosis can only be made on the basis of microscopic examination. The relative frequency of isolated neurinoma of the optic nerve is stressed and its slow and usually benign evolution is described. Radiotherapy is of no value and the only treatment is surgical excision. This is always indicated because of the possibility of malignant changes and because of changes in the optic nerve resulting from pressure. The results of surgery are generally good; the exophthalmos disappears, usually leaving a slight degree of enophthalmos with slight limitation of motion. Visual acuity improves with disappearance of the papilledema.   Phillips Thygeson.

Saebø, Johan. Lipoma conjunctivae in three generations. Acta ophth. 26:447-450, 1948.

Lipoma of the conjunctiva at the outer angle of the right orbit is reported in

three generations. The inheritance is dominant and the tumor was larger in each succeeding generation. (2 figures, 1 table.) Ray K. Daily.

Suárez Villafranca, M. R. **Intraocular and orbital tumors.** Arch. Soc. oftal. hispano-am. 9:67-90, Jan., 1949.

The diagnosis of eight intraocular and six orbital tumors is discussed. The slow evolution of sarcoma of the choroid in contradistinction to the rapid growth of sarcoma of the ciliary body is noteworthy, and the fundus picture of exudative retinitis in the case of intraocular cysticercus is worth remembering. (16 figures.) Ray K. Daily.

17

INJURIES

Atkinson, W. S. **Delayed keratitis due to mustard gas (dichlorodiethyl sulfide burns).** Arch. Ophth. 40:291-301, Sept., 1948.

Late corneal lesions develop more frequently in cases with greater exposure to mustard gas and in those of greater susceptibility to it. The condition is aggravated if the eyes are bandaged during the acute stage that follows exposure to mustard gas. After recovery from acute symptoms, which in severe burns last from two to eight months, and sometimes longer, the patient is practically free from symptoms for eight years or more. Photophobia, lacrimation and failing vision mark the onset of the late corneal lesions. Superficial haze of the cornea just beneath the epithelium in the area of the palpebral fissure, lines or striae in the substantia propria and folds in Descemet's membrane may precede the formation of deposits of cholesterol and fat. These deposits increase in size, break through the epithelium and produce an exacerbation of the symptoms of irritation. Later, there is a heaping up of hard,

degenerative tissue on the cornea. The scarred cornea is so irregular that vision is improved only with contact lenses. There are also pale, triangular patches on either side of the cornea in the area of the palpebral fissures that resemble lesions produced by surface application of beta radiation. Intracorneal hemorrhages occur and seem to arise from the large varicose vessels, which extend up to the limbus. Recognition of the late effects of mustard gas is important, so that claims of veterans of World War I may be justly handled. Ralph W. Danielson.

Knudtzon, Karsten. **The prognosis of scotoma helieclipticum. Follow-up of 47 patients injured in July 1945.** Acta ophth. 26:469-494, 1948.

A review of the literature precedes the tabulated report of the ocular examination of 47 patients 18 months after injury by a solar eclipse. Forty had ocular damage. The damage produced by watching a solar eclipse without adequate protection is severe and permanent and justifies public warning before an eclipse. The usual inadequate sun glasses give a false sense of security. Knudtzon also warns against Bates' and Huxley's advice to accustom the eyes to direct sunlight. Ray K. Daily.

Lindblom, K. **Localization of foreign bodies in the eye by bone free radiography.** Acta ophth. 36:439-440, 1948.

Lindblom describes his mofidication of the Vogt method of bone-free radiography for localization of foreign bodies in the anterior ocular segment. (4 figures.) Ray K. Daily.

Minton, Joseph. **Occupational diseases of the lens and retina.** Brit. M. J. pp. 392-394, March 5, 1949.

Protective care of the workers must be taken, the author states, or soon there will be reports of severe anemias and

cataracts in industries in which workers are exposed to molten glass or metal, ultraviolet radiation, high-tension electric currents and Xrays.

<div align="center">Theodore M. Shapira.</div>

Saebø, Johan. **Automutilatia bulborum. A rare case of self-mutilation in an epileptic.** Acta ophth. 26:451-453, 1948.

An epileptic, 25 years old, destroyed both of his eyeballs, apparently painlessly, under the illusion that this action would lead to a cure of his epilepsy and subsequent restoration of vision. He sectioned the upper lids and conjunctiva with the nail of the index finger, and then introduced the finger behind the eyeballs, and emptied them of their contents.

SYSTEMIC DISEASE AND PARASITES

Bucek, Alois. **Stevens Johnson syndrome.** Lekarske Listy 4:203-204, May, 1949.

A case of Stevens-Johnson syndrome in a boy aged 2½ years is presented with two striking pictures.

<div align="center">F. H. Haessler.</div>

Cass, E. **Reiter's disease.** Arch. Soc. oftal. hispano-am. 9:176-179, Feb., 1949.

To the 200 cases of Reiter's disease reported in the literature the author adds one more case. The general examination was negative and therapy ineffective. The distinguishing feature was the rapid alleviation of some symptoms and the appearance of others, and the occurrence of interstitial keratitis, which is reported for the first time.   Ray K. Daily.

Croom, J. H., and Scott, G. I. **Retinal and vascular damage in long-standing diabetes.** Lancet 1:555-558, April 2, 1949.

The authors examined 60 patients who had diabetes from 15 to 26 years. Fifteen

patients were free of any degenerative disease, they had neither retinopathy nor vascular changes, although one of them had had diabetes over 26 years. Only 18 patients presented typical diabetic retinopathy and 9 of them had normal retinal arteries, whereas the others had only slight arteriosclerotic or hypertensive changes. Some factor other than arteriosclerosis must be responsible for the retinopathy. The Kimmelstiel-Wilson syndrome or intercapillary glomerulosclerosis characterized by hypertension with edema of nephrotic type, massive albuminuria and renal or cardiac decompensation was present in two patients only.

<div align="center">R. Grunfeld.</div>

Curtis, A. C., and Grekin, R. H. **Sarcoidosis: treatment with calciferol and dihydrotachysterol.** Tr. Am. Acad. Ophth. pp. 344-351, March-April, 1949.

Of 19 patients with sarcoidosis (4 had ocular lesions), 9 of whom were treated with calciferol and 5 with dihydrotachysterol, 3 were considered cured and 5 were improved. Both drugs increase the serum calcium and the excretion of serum phosphorus. Toxic reactions are not infrequent and occur less often if the calcium and nonprotein nitrogen is increased. It is not yet known which drug is more desirable. Both seem to produce approximately the same results. The toxic symptoms apparently occurred more slowly in patients treated with dihydrotachysterol. The optimal dose of calciferol is between 150,000 and 300,000 units daily; 3.75 mg. dihydrotachysterol is usually administered daily for three days and then reduced to 1.5 mg. The epithelioid cell reaction in sarcoidosis is apparently due to a phospholipid abnormality and the beneficial effect of calciferol and dihydrotachysterol is associated with the increased secretion of phosphorous. The authors believe that this treatment is not the ultimate one, but consider it more effective

than other treatments now in use.

Chas. A. Bahn.

Giardini, A. **Effect of methylthiouracil on the manifestations of Basedow's disease.** Boll. d'ocul. 27:706-721, Nov., 1948.

Seventeen Basedow patients were treated with methylthiouracil and the gravity of their signs and symptoms was listed in tables which contained the exophthalmometer measurments, estimations of the lid edema, 12 eye signs of Graves, Stellwag, Dalrymple, Gräfe, et altera, pupillary changes, and the basal metabolism figures. About half of the patients showed a slight reduction of their exophthalmos. Patients with reduced dark adaptation did not respond to methylthiouracil unless high additional doses of vitamin A were administered. (2 tables, references.)   K. W. Ascher.

Iribarren, R. **A case of subconjunctival filaria Loa loa.** Arch. de oft. de Buenos Aires 23:302-308, Oct., 1948.

This nematode and accompanying symptoms are described at length. A case is described in which a cyst containing the filaria was removed from a conjunctival sac and other microfilaria were demonstrable in the blood-stream. (4 figures, references).   Edward Saskin.

Scheie, H. G. **Ocular changes associated with scrub typhus.** Arch. Ophth. 40:245-267, Sept., 1948.

The eyes of 451 patients with scrub typhus were studied weekly for evidence of disease. Conjunctival injection was present in 38 percent, and subconjunctival hemorrhages in 6.4 percent. Ecchymosis, eschar of the eyelid, fixation nystagmus were seen occasionally. There was engorgement of retinal veins in 67 percent, retinal edema in 36; retinal hemorrhages and retinal exudate, uveitis and vitreous opacities in a few patients. Pathologic studies of eyes obtained at autopsy revealed that a subacute diffuse choroiditis was the basic lesion. The fundus changes not seen in other febrile diseases in this area were frequently helpful in diagnosis. The lesions in the eye are a fair index of convalescence.

Ralph W. Danielson.

Woods, A. C. **Sarcoidosis: the systemic and ocular manifestations.** Tr. Am. Acad. Ophth. pp. 333-343, March-April, 1949.

After a historical review, a brief résumé of the extraocular symptoms is given. Among these are increased sedimentation rate, increased globulin fraction and anergy to as much as 10 mg. tuberculin. Negroes are more susceptible in the ratio of 6 to 1. The ocular lesions are chronic granulomatous processes with epithelioid cell nodules. Although the individual lesions may be benign, secondary glaucoma and ocular atrophy are not infrequent. The eyes were involved in 44 of 94 cases of sarcoidosis. The eyes are frequently involved early in the disease, which may be associated with uveo-parotid fever and Mikulicz syndrome. Some authors consider that 5 to 10 percent of uveitis is due to sarcoidosis. Almost all parts of the eye may be involved. Nodular uveal lesions with interlacing vascular patterns and large gray precipitates are frequent. Primary choroidal and retinal lesions are rare.   Chas. A. Bahn.

19

CONGENITAL DEFORMITIES, HEREDITY

Albertto, Benjamin. **Marfan's syndrome.** Arch. de oft. de Buenos Aires 23:240-252, Sept., 1948.

A case of Marfan's syndrome in a girl, 12 years of age, is presented in great detail.   A. G. Wilde.

Bernoulli, R. **The mechanism of persistence of the hyaloid artery.** Ophthalmologica 117:169-179, March, 1949.

A rare congenital anomaly in a seven-year-old boy is described. The right eye was highly myopic but seemed to have adequate vision. The left eye was slightly microphthalmic. A heavy vessel-bearing strand of gray tissue originated in the region of the disc, traversed the vitreous cavity forward, downward and laterad and was inserted on the posterior surface of the lens a little below the posterior pole. No blood vessels could be made out in the retina which appeared to occupy a normal position. The strand in the vitreous is interpreted as a persistent hyaloid artery with hypertrophic glial sheaths. This overdevelopment of the glial sheaths probably prevented the development of the retinal vessels.   Peter C. Kronfeld

Broendstrup, J. M. Posterior embryontoxon in three generations. Anomaly of development of the anterior chamber of the eye with annular opacity of the cornea and membrane before the chamber angle. Acta ophth. 26:495-507, 1948.

The literature is reviewed and a family with embryontoxon reported. The bilateral malformation consisted of a massive adhesion between the iris and cornea. Around the entire circumference there was a whitish gray homogeneous peripheral band-like thickening on the posterior surface of the cornea, 0.5 to 2 mm. wide with a sharp serrated pupillary edge, and a peripheral boundary that faded gradually into clear cornea. There was definite hypoplasia of the iris and its stroma seemed to fuse with the corneal band. At 35 years of age glaucoma was discovered in one eye. Seven cases of this anomaly occurred in three generations of the family. All affected members were fair, short, blue eyed, and had high cheek bones. The unaffected members were dark and tall. (5 figures.)   Ray K. Daily.

Esteban, A., and Wolf, J. A. Bilateral aniridia with ptosis and embryontoxon.

Arch. de oft. de Buenos Aires 23:141-148, July-Aug., 1948.

A twenty-eight-year old woman who had one son with aniridia and another with congenital heart defect had bilateral ptosis with enophthalmos, congenital bilateral aniridia and nystagmus. The marked photophobia was mitigated somewhat by her ptosis. She had no strabismus, and convergence was normal. The cornea showed a peripheral clouding 2 to 4 mm. wide in the superficial layers resembling an arcus senilis, but more irregular in outline. There was anterior and posterior cataract. The visual acuity was limited to counting fingers at two meters.
                                A. G. Wilde.

Hallermann, W. "Bird-face" due to deformation of the mandible and congenital cataract. Klin. Monatsbl. f. Augenh. 113: 315-318, 1948.

Two cases of congenital malformation of the mandible with considerable shortening of its body which leads to the appearance of "bird face" are reported. Both patients had had bilateral congenital cataracts in each eye. It is not known whether the two abnormalities are related. (4 figures.)   Max Hirschfelder.

Lowe, R. F. The eyes in mongolism. Brit. J. Ophth. 33:131-175, March, 1949.

Mongoloid facies and almond shaped palpebral apertures do not invariably occur in the syndrome mongolism. One of the most important signs is the general retardation of growth affecting all the tissues of the body even to the extent of retention of fetal characteristics throughout life. In 67 patients, of which 40 were over 25 years of age, the skulls and all the skull bones examined exhibited a marked retarding of growth. Four skulls even had persistent frontal sutures. The diameters of the orbits were small and the inclination of the axis was 75 degrees

instead of the normal 45. This brings about a palpebral aperture which is more oblique and shorter than the normal. Epicanthus is normal in babies and disappears in the first few years. In mongolism it remains a little longer and is almost always gone by the 12th year. The lids and lacrimal systems are usually normal. The iris presents two characteristic changes: a general poverty of stromal fibers and noticeable depigmentation. Speckling of the iris is common. Arcuate lens opacities, the most common, develop during fetal life owing to the presence of abnormal capsulo-pupillary vessels, sutural opacities occur in the anterior Y sutures of the fetal nucleus and flake opacities are found in the juvenile and adult nuclei. About one third of subjects had very high myopia. Nystagmus was found in nine and in only 2 was it of cerebral origin. It is not considered characteristic of mongolism. Strabismus occurs about 20 times as often as in the general population. (23 figures.)

Morris Kaplan.

Lutman, F. C., and Neel, J. V. **Inheritance of arachnodactyly, ectopia lentis and other congenital anomalies (Marfan's syndrome) in the E family.** Arch. Ophth. 41:276-305, March, 1949.

Marfan's disease is a syndrome which in its fullest expression is characterized by an elongate, slender body build, especially evident in the extremities, skeletal deformities (kyphosis, scoliosis, pigeon breast, pes planus, hammer toes), dolichocephalic skull, poorly developed and hypotonic musculature, laxity of the joints and ligaments, scanty subcutaneous fat, malformation of the ears, malformations of the lungs, congenital heart disease, and ocular anomalies, especially ectopia lentis. There is great variability in the degree to which these traits are manifest.

The clinical records of several hundred visits by members of the E family have been accumulating at the Strong Memorial and Rochester Municipal Hospitals since 1928. In 1941, an attempt was made to reëxamine all the members who had hospital records. In a kinship of 40 persons, 17 members probably had Marfan's syndrome (arachnodactyly, ectopic lentis, indications of cardiac abnormalities and other congenital defects). There was a great variability in the expression of the syndrome in the affected members of the kinship. In addition to classic cases, there existed in this one family members so mildly affected that the diagnosis would be unsuspected or in doubt were it not for their genetic background. Ocular anomalies observed in all persons studied were, in addition to ectopia lentis or coloboma of the lens, abnormal zonular fibers, an iris lacking in the usual surface trabeculae and crypts, deficiencies of uveal pigment, particularly at the periphery of the iris, and amblyopia. In several cases there were other ocular defects. The syndrome is inherited as though due to one or more dominant autosomal genes. Although a final decision is not possible, the bulk of the evidence suggests that the entire syndrome may be due to one gene only whose expression is greatly influenced by other genetic, and possibly by environmental, factors.

Ralph W. Danielson.

Straith, C. L., and Lewis, J. R. **Associated congenital defects of the ears, eyelids and malar bones (Treacher Collins syndrome).** Plast. and Reconstruct. Surg. 4: 204-213, March, 1949.

In addition to a review of the literature, which is scanty, four cases of Treacher Collins syndrome are reported. The characteristics are as follows: flattened malar eminence, deficient lower orbital margin, oblique palpebral fissures,

bilateral notches in the outer third of the lower eyelids, eyelashes absent on medial two-thirds of lower eyelids, receding chin, and high, narrow, prominent front teeth, bilaterally deformed external ears, with frequently associated abnormalities of the external auditory meatus and loss of hearing. Plans for the plastic repair of these defects are discussed. Alston Callahan.

20

HYGIENE, SOCIOLOGY, EDUCATION, AND HISTORY

Eames, T. H. **The effect of glasses for the correction of hypermetropia and myopia on the speed of visual perception of objects and words.** J. Educational Research 42:534-540, March, 1949.

In 100 children an increase in speed of work perception followed the use of glasses for correction of refractive errors. The correction of lower degrees of hypermetropia than of myopia tends to produce increment in a larger percentage of cases per dioptric level. F. H. Haessler.

Jokl, A. **Death from eye disease and occurrences of death in ophthalmological practice.** Ophthalmologica 117:129-146, March, 1949.

The author reviews the eye diseases which have caused the patient's death, either directly or through circumstances which were the direct sequel of the eye disease or intimately connected with it. The diseases are grouped under the following headings: hemorrhages from the conjunctiva in hemophilia and from vascular tumors and bacterial diseases that gained entrance to the body through the conjunctiva or the lids, perforating injuries, or orbital cellulitis. The severe systemic intoxication due to the local application of "lash lure" is mentioned. Well known examples of death after operations are the fatal outcome of dacryocystectomies in chronic suppurative dacryocystitis and of enucleations in panophthalmitis. The malignant primary tumors of the eye and its adnexa are discussed in detail. Fear of blindness or unrelieved neuralgic pain may drive a patient to suicide. The first pair of bifocals makes the patient more liable to meet with an accident. Peter C. Kronfeld.

Mercier, Armand. **Visual aptitudes in railroad and aviation employees.** Ann. d'ocul. 182:24-31, Jan., 1949.

The relative merits of the requirements are discussed. The author believes that railroad employees require better sight than aviators. Chas. A. Bahn.

Sachs, M. **Nearly one hundred years of the ophthalmoscope.** Arch. Ophth. 40: 268-272, Sept., 1948.

This paper gives interesting facts about von Helmholtz and describes incidents in the discovery of the ophthalmoscope. Ralph W. Danielson.

NEWS ITEMS

Edited by DONALD J. LYLE, M.D.
601 Union Trust Building, Cincinnati 2

News items should reach the editor by the 12th of the month but, to receive adequate publicity, notices of postgraduate courses, meetings, and so forth should be received by the editor at least three months before the date of occurrence.

DEATHS

Dr. Harry Monroe Hendershott, Portland, Oregon, died March 26, 1949, aged 69 years.

ANNOUNCEMENTS

EGYPTIAN MEDAL FOR SCIENTIFIC WORK

To encourage scientific ophthalmic work, the Ophthalmological Society of Egypt will award each year a gold medal for the most valuable contribution of the year.

The competition is open to all members of the society of less than 20 years' practice, whether living in Egypt or outside of the country. Candidates desiring to enter the prize competition should submit their theses, in three typed copies, not later than the first of December each year.

In making the award, the committee will consider: (1) The originality of the work in its conception and execution; (2) its application to the major problems of ophthalmology; and, (3) general presentation.

Further information may be obtained by addressing: Dar El Hekma, 42 Kasr El Ainy Street, Cairo, Egypt.

CALIFORNIA POSTGRADUATE COURSE

The University of California Medical School, San Francisco, is offering a postgraduate course in ophthalmology from September 12th through September 17th. The course is open only to graduates of medical schools approved by the Council on Medical Education and Hospitals of the A.M.A. The fee for the course is $60.00, payable at the time of enrollment.

Dr. Frederick C. Cordes, clinical professor of ophthalmology, University of California Medical School, is general chairman of the course. Officers of instruction will be: Dr. Samuel D. Aiken, Dr. Crowell Beard, Dr. Dudley P. Bell, Dr. George S. Campion, Dr. Joseph W. Crawford, Dr. C. Allen Dickey, Dr. Owen C. Dickson, Dr. David O. Harrington, Dr. Margaret Henry, Dr. Michael J. Hogan, Dr. Bertram V. A. Low-Beer, Dr. Robert N. Shaffer, Dr. Joseph G. Smith, and Dr. Phillips Thygeson.

Further information may be obtained by addressing: Dr. Stacy R. Mettier, head of postgraduate instruction, medical extension, University of California Medical Center, San Francisco 22, California.

Preceding the postgraduate course in ophthalmology will be a course in otorhinolaryngology, September 5th through 9th.

TORONTO OFFERS GRADUATE TRAINING

The University of Toronto, Faculty of Medicine, offers a postgraduate course in ophthalmology extending over three years. The graduate instruction in ophthalmology in the teaching hospitals in Toronto has been coördinated under the direction of the university. The first year on a fellowship, the value of which is approximately $1,400, the student spends in one of the basic sciences of ophthalmology, and the final two years are spent on the intern service of one or more of the university teaching hospitals. Approximately four hours of didactic teaching are arranged for the students by members of the staff each week from October to May. On Saturday morning, staff ward rounds are made at the Toronto General Hospital and are attended by the interns from the other teaching hospitals.

A sound knowledge of neurology and metabolic diseases is desirable. The following courses are given: geometric and physiological optics, physiology of the eye, principles and practice of biomicroscopy, perimetry, ocular therapeutics, medical ophthalmology, pathology of the eye, bacteriology and external diseases of the eye, embryology and developmental anomalies of the eye, ocular motor anomalies, anatomy of the orbit, skull, and brain, radiological ophthalmology, industrial ophthalmology, intraocular and plastic surgery, pathology of the visual pathways, refraction, neuro-ophthalmology, glaucoma. Senior interns are given instruction in the preparation and presentation of scientific papers.

The fee for instruction is $50.00 per year payable to the chief accountant, University of Toronto. An application for appointment may be made to the professor of ophthalmology, Faculty of Medicine, University of Toronto. Appointments are made in December to commence on the following July 1st.

ORTHOPTIC TRAINING COURSE

The Rochester (New York) Orthoptic Center is receiving applications for its next training course for orthoptic technicians. The course is accredited by the American Orthoptic Council. Information may be obtained from the Rochester Orthoptic Center, 208 North Goodman Street, Rochester 7, New York.

MISCELLANEOUS

LIONS CLUB SCHOLARSHIPS

On June 21st, the Lions Club of New York presented four $500 scholarships to graduate students of New York University College of Medicine who

are planning to become eye specialists. The presentation took place at the annual Ladies' Day luncheon at the Savoy Plaza.

Walter Hoving, president of the Hoving Corporation, in behalf of the Lions Club, handed a $2,000 check to Dr. Daniel B. Kirby, professor of ophthalmology, New York University College of Medicine. Dr. Kirby said the funds would enable four students to undertake research projects, adding that even such small sums of money might be instrumental in obtaining important results.

The four students who will receive the scholarships are Dr. Irwin Cohen, Dr. Thomas Heslin, Dr. James Mayer, and Dr. Arthur Smith.

Ernest R. Fryxell, chairman of the Lions Club Blind Aid and Eye Conservation Committee, announced that the organization would suggest to the 7,203 Lions Clubs throughout the country that they undertake similar scholarships for ophthalmologists.

Earlier recipients of the Lions Club of New York scholarships are: Dr. Edward P. Danforth, Dr. Charles Goldsmith, Dr. Jonathan L. Harris, and Dr. Hugh McGree for the year, 1946; Dr. Edward Buckley, Dr. George R. Kolodny, Dr. Nathaniel Robinson, and Dr. Horace Shreck, for 1947; Dr. Goodwin Breinin, Dr. Edwin Kent, Dr. Walter Mayer, and Dr. Charles Toomey, for 1948.

BETTER VISION INSTITUTE

New members present at the annual meeting of the Better Vision Institute, June 10th, at the Park Lane Hotel, New York, were John Wiseman of Wiseman Optical Company, London, England; Tom Hood and Fred Soden of Continental Optical Company; Dr. John J. Brown of Perth Amboy, New Jersey; and Ray Farnum of Bausch & Lomb Optical Company.

Elections were held of new directors to serve two-year terms, and new finance committee members to serve for one year.

CAROLINAS MEETING

On September 12th through 15th, at the Hotel Poinsett, Greenville, South Carolina, the North Carolina Eye, Ear, Nose, and Throat Society and the South Carolina Society of Ophthalmology and Otolaryngology will hold a joint meeting. The following program will be heard:

Dr. A. D. Ruedemann, professor of ophthalmology, Wayne University, Detroit, Michigan: "The differential diagnosis between unilateral and bilateral ocular protrusion"; "The end results with new radium-D applicator in comparison to radon"; "Ocular manifestations of allergy."

Dr. Peter C. Kronfeld, Department of Ophthalmology, Illinois Eye and Ear Infirmary, University of Illinois, Chicago: "Differential diagnosis of acute glaucomas"; "Prognosis of retinal detachment"; "Newer drugs in ophthalmology."

Dr. Rudolph Aebli, professor of ophthalmology, New York University, Bellevue Medical Center, Post-Graduate Medical School, New York: "The

relationship of muscle imbalances to the palpebral aperture and pseudoptosis"; "Principles of ocular muscle surgery"; "Congenital muscle anomalies."

Dr. Carl C. Johnson, associate, Department of Ophthalmology, Harvard University, Boston: "Surgical treatment of ptosis"; "The diagnosis and surgical treatment of glaucoma."

Dr. Preston C. Iverson, New York: "Neoplasms of the lip, nose, and eyelid and plastic repair of the lesions"; "Congenital deformities of the face."

Dr. Louis H. Clerf, Philadelphia: "Cough viewed from otolaryngologic standpoint"; "Paralysis of larynx: Surgical treatment"; "Malignant neoplasms of larynx."

Dr. Kenneth M. Day, Pittsburgh: "Clinical management of deafness"; "Meniere's disease."

Dr. Russell A. Sage, Indianapolis: "Diseases of the mouth and tongue."

Officers of the South Carolina Society of Ophthalmology and Otolaryngology are: President, Dr. Pierre G. Jenkins; vice-president, Dr. Murdock Walker; secretary-treasurer, Dr. Roderick Macdonald.

Officers of the North Carolina Eye, Ear, Nose, and Throat Society are: President, Dr. James Harrill; vice-president, Dr. G. M. Billings, secretary-treasurer, Dr. MacLean B. Leath.

WEST VIRGINIA OFFICERS

The officers of the West Virginia Academy of Ophthalmology and Otolaryngology are: President, Dr. Garnett P. Morison, Charles Town; 1st vice-president, Dr. Charles T. St. Clair, Jr., Bluefield; 2nd vice-president, Dr. Arthur C. Chandler, Charleston; treasurer, Dr. Frederick C. Reel, Charleston; secretary, Dr. Melvin W. McGehee, Huntington; directors, Dr. Eugene C. Hartman, Parkersburg, and Dr. Ivan Fawcett, Wheeling.

PERSONALS

To GIVE FOURTH PROCTOR LECTURE

On Friday evening, September 16th, Dr. Jonas S. Friedenwald, Baltimore, will deliver the fourth annual Francis I. Proctor Lecture on Ophthalmology at the University of California Medical School, San Francisco. The subject of Dr. Friedenwald's address will be "Further studies on diabetic retinopathy."

RESEARCH ON CORNEAL TRANSPLANTS

Dr. A. E. Maumenee, head of the Department of Ophthalmology, Stanford University School of Medicine, San Francisco, will do research work on corneal transplants under a contract with the National Advisory Council of the U. S. Public Health Service.

In announcing the receipt of the grant, Dean Loren R. Chandler of the medical school said that the funds include an allowance for a research fellow and that applications for the fellowship are requested by the medical school. The research grant is for one year but is subject to renewal.

THERAPEUTIC RESULTS IN ADVANCED CHRONIC SIMPLE GLAUCOMA WITH TELESCOPIC FIELDS*

SYLVAN BLOOMFIELD, M.D., AND LEO KELLERMAN, M.D.

New York

In the treatment of chronic simple glaucoma it is generally accepted that surgery is indicated when medical therapy proves unsatisfactory. Reese[1] and, more recently, Kronfeld and McGarry[2] have demonstrated statistically that such operations are most successful early in the course of the disease, and that the results of surgery on eyes with advanced glaucomatous damage are generally poor. This is in agreement with the opinion expressed by Gradle[3] and others, that operation on an eye with advanced glaucoma is extremely hazardous.

Another observation concerning eyes in an advanced stage of glaucoma is of interest. Reese, in a footnote appended to his paper,[1] noted that such eyes, when reduced to telescopic fields, often seemed to retain central vision for long periods although their ocular tension might be uncontrolled. Kronfeld and McGarry[2] have stated that "it seems highly probable, however, that the chances of survival of the center of the field are not much poorer under nonnormalization than under normalization of tension."

If it is true that glaucomatous eyes with markedly restricted central fields retain their residual function in spite of elevated tension, and that operations for reducing tension in such eyes are dangerous, it would seem that surgery in these cases may acually be contraindicated. Such a conclusion, however, is opposed to the widespread opinion that in any eye an abnormally high intraocular pressure that does not respond to medical therapy should be treated surgically. The purpose of this paper is to evaluate statistically the advisability of surgical intervention in eyes reduced to telescopic fields by advanced chronic simple glaucoma that is medically uncontrolled.

For this study, the course of a series of unoperated eyes with advanced chronic simple glaucoma was investigated. Only those eyes were considered that had central fields reduced in all isopters to 10 degrees or less from fixation at their widest meridian. These fields were all measured on the tangent screen at one meter, with standard-sized objects. A few eyes were included in this group in which, in addition, small temporal islands of field were present but completely separated from the central field by at least 10 degrees. In none of these eyes was vision reduced to less than 20/200. This limit was decided upon so that later decreases in vision might be readily detected. Finally, all of the eyes included in this study showed tensions of over 35 mm. Hg (Schiøtz), on three or more occasions, to indicate the inadequacy of medical treatment in each case. The problem such uncontrolled tension presented was met in certain of these cases by resort to surgery, and in other instances simply by continuation of miotic therapy. A comparison of the results of each of these methods of treatment is the basis of this study.

The records employed for this investigation were obtained from the ward services of

---

two large metropolitan ophthalmic hospitals whose files for the past eight years were reviewed. All eyes that fulfilled the above criteria were considered for this study. However, since relatively few eyes fulfilled all these conditions and since the records of many otherwise eligible cases were not sufficiently complete for critical evaluation, only 41 eyes were found suitable for consideration.

Of these 41 eyes, 19 subsequently underwent surgery to relieve a recurrently high tension that did not respond to miotic therapy. The remaining 22 eyes were not operated upon, although the tension in each case was inadequately controlled medically according to the criteria outlined above. The range of ages of the patients in the operated group was from 30 to 77 years, and averaged 62 years. The ages of the patients in the unoperated series was from 38 to 79 years, and averaged 65 years.

The preoperative visual acuities in the operated eyes ranged from 20/30 to 20/200. Of the 19 eyes in this group, 11 had vision of better than 20/70, and 8 had visual acuities of 20/70 or less before operation. The range of visual acuity in the 22 eyes that were not operated upon was from 20/30 to 20/200. Of these, 11 had visual acuities of better than 20/70, and 11 had acuities of 20/70 or less, at the beginning of the period under consideration in this study.

The range of tension in the eyes in each series at the beginning of this period was also quite similar. Thus the conditions of the eyes in each of these two groups, before surgery was applied to one of them, were sufficiently alike to permit a valid comparison of the results of alternative methods of therapy.

In evaluating the results of surgery, only the response to the first operation was considered in those three cases where several procedures were performed. The follow-up period under consideration was terminated before the second operation on these eyes, to permit attention to be focused in this study

on the results of a single operation in these late glaucomatous eyes rather than on the cumulative traumatic effects of many surgical procedures. However, the occurrence of postoperative complications did not exclude any eye from consideration inasmuch as they were considered relevant to the problem of determining the hazards such surgery entails. The operations done comprised 5 Elliot trephining operations, 2 modified Lagrange operations, 1 basal iridectomy, 8 iridencleisis operations, 2 iridencleisis with sclerectomy procedures, and 1 cyclodiathermy operation.

In evaluating the results of the treatment of these eyes, it was felt that the primary consideration was the eventual effect on visual acuity. Since all the eyes under consideration had initial fields limited to 10 degrees or less from fixation, further field restrictions would frequently have been difficult to distinguish and certainly, from the patient's point of view, would be far less important than the actual vision retained. All visions were recorded with refractive correction where so improvable.

It was usually very difficult to establish accurately the exact cause for the reduction in visual acuity that occurred in many of these eyes. Therefore, no attempt was made in this investigation to determine to what degree visual loss was due to cataractous changes in the lens, progressive neuroretinal degeneration, or vascular pathologic conditions. It seemed valid to assume that in these two series of similar eyes the incidence of such senile and glaucomatous pathologic processes would be statistically equivalent except for the surgery performed on one group, which would affect ocular structures, and the subsequent course of the glaucoma, only in the operated series.

STUDY OF OPERATED EYES

Of the 19 eyes operated upon, 11 (58 percent) showed some loss in visual acuity at the first postoperative examination, and that loss ranged from one line on the standard Snellen chart to loss of light perception, in

one case. From the point of view of useful vision, it may be noted that, whereas none of these 19 eyes preoperatively had less than 20/200 vision, the first acuity recorded post-operatively had fallen below this level in 6 (32 percent) of all these eyes.

The follow-up period for these operated eyes varied from 2 months, in one case that was reduced to perception of hand move-

of that time. Thus, for the periods recorded, it is noteworthy that only 3 of these 19 eyes retained a visual acuity equal to that present preoperatively, and 16 (84 percent) of the total suffered some visual loss. In the latter group, 9 eyes or (47 percent) of the total number operated upon were reduced in visual acuity to less than 20/200 by the end of their follow-up period. Of these 9 eyes

Fig. 1 (Bloomfield and Kellerman). Summary of visual status of operated and unoperated eyes.

	OPERATED	UNOPERATED
TOTAL NUMBER OF EYES IN EACH GROUP	19	22
NUMBER OF EYES WITH INITIAL VISION OF BETTER THAN 20/70.	11	11
NUMBER OF EYES WITH INITIAL VISION OF LESS THAN 20/70.	8	11
AVERAGE FOLLOW-UP PERIOD.	28 mos.	24 mos.
NUMBER OF EYES WITH SOME LOSS OF VISION. AFTER FOLLOW-UP.	16	8
PERCENTAGE OF EYES WITH SUCH LOSS.	84%	36%
NUMBER OF EYES WITH VISION REDUCED TO LESS THAN 20/200 WITHIN FOLLOW-UP PERIOD	9	3
PERCENTAGE OF EYES WITH SUCH SEVERE VISUAL LOSS	47%	14%

ments in that period, to 6 years. The average follow-up interval for the group was 2 years and 4 months. During this postoperative period, 11 of these 19 eyes showed satisfactory control of tension, as indicated by a tension range consistently below 35 mm. Hg (Schiøtz). In the remaining 8 eyes (42 percent) the tension remained uncontrolled postoperatively, even with supplementary medical treatment.

Although the follow-up period recorded for this operated series is not long, several interesting facts are revealed by a study of the visual status of these eyes at the end

with markedly reduced vision, 6 were eyes in the group of 8 with tension uncontrolled postoperatively and the remaining 3 were among the 11 eyes whose tensions were apparently successfully controlled by operation. Thus, of the eyes whose tension was uncontrolled, 75 percent showed a loss of visual acuity to less than 20/200, and of the postoperatively controlled group, 27 percent showed such extreme loss in acuity.

The small number of cases operated upon does not permit many conclusions to be drawn from a more detailed analysis of these results. Although the two eyes with highest

preoperative tensions were respectively reduced in visual acuity from 20/30 and 20/40 to perception of hand movements and finger counting, such a possible relationship of high preoperative tension to poor postoperative result is not borne out in other cases. Similarly, there seemed to be no correlation of degree of loss of vision to the age of the patient. In general, the immediate postoperative loss of vision seems to have been less in those eyes which underwent iridencleisis, but too few operations of the different types were performed to permit comparison of the results of the various procedures done on these advanced cases of glaucoma.

To determine to what degree these surgical results were influenced by systemic diseases that might predispose to operative complications, the blood pressure and fasting blood sugar recorded in each case at the time of operation were noted. In none of the 17 patients that underwent surgery was vascular hypertension present. In 3 of the patients, a mild degree of diabetes mellitus was recorded.

Four eyes of these 3 diabetic patients were included in the operated group. Three of these eyes showed no immediate postoperative loss of vision, which, as demonstrated above, is a better immediate operative result than that which occurred in the group as a whole. During follow-up periods similar to those of other patients in this study, a drop in visual acuity to less than 20/200 occurred in 2 of these 4 eyes, or 50 percent. As was noted above, this severe degree of visual loss was recorded in 47 percent of the whole operated group. It would, therefore, seem that the presence of diabetes mellitus in 3 of the operated patients did not appreciably affect the statistical evaluation of surgical results in this series.

It also seemed desirable to estimate the possible influence on these results of the varying technical skills of different operators. All these cases were operated upon in 1 of 2 large metropolitan ophthalmic hos-

pitals. Nine of these 19 eyes were operated upon by experienced ophthalmologists who were on the attending staffs of these institutions. The other 10 eyes were operated upon by resident physicians supervised and assisted in each instance by a member of the attending staff. An immediate loss of some visual acuity was noted postoperatively in 4 of the eyes operated upon by the residents, and in 7 of the eyes operated upon by the members of the attending ophthalmological staffs. After the follow-up periods noted, a drop in visual acuity to less than 20/200 was noted in 4 of the eyes operated upon by the residents, and in 4 of the eyes operated upon by members of the attending staffs. It would, therefore, appear that in this series, the operative results obtained by the residents was no worse than that obtained by the attending ophthalmologists, and that consequently the technical experience of the operators did not significantly affect the statistical results in this operated group of eyes.

STUDY OF NONOPERATED EYES

Of the 41 eyes with telescopic fields due to advanced chronic simple glaucoma here studied, 22 eyes in 20 patients were not operated upon although their tensions were inadequately controlled by medical treatment, according to the standard previously noted. These cases were closely followed for periods ranging from 8 months to 5 years, and averaged a recorded course of slightly more than two years. This approximates the follow-up period recorded for the group of comparable eyes that were operated upon, as previously noted.

During these periods, in spite of apparently inadequate therapy limited to the local instillation of miotics, a reduction in vision of any degree was noted in only 8 (36 percent) of these eyes. This visual loss ranged from one line on the standard Snellen chart to loss of light perception, in one eye. In only 3 of these eyes, 14 percent of all the unoperated eyes, was the visual acuity reduced below 20/200. It may be recalled that in the

eyes that were operated upon, 84 percent showed some visual loss over a comparable follow-up interval and 47 percent of the whole operated group had visual acuities reduced below 20/200 during that time.

INITIAL AND RESULTING VISION

A correlation was sought between the initial visual acuity in each eye of the two series and the vision eventually present. Among the operated eyes, a reduction in vision of at least one line on the Snellen chart occurred with equal frequency in the group with preoperative vision of better than 20/70 and that with initial acuities of 20/70 or less. This was true both for the results found at the first postoperative examination of acuity and for those recorded after the stated follow-up periods. Of course, the occurrence of further visual loss resulted more frequently in disablingly low acuity in the group with initially poorer vision. Similarly, in the group of unoperated eyes, the incidence of further visual loss during the period of this study was not significantly different in those eyes with initial acuity of better than 20/70, than in those whose vision at the beginning of the period of observation was already reduced to 20/70 or less.

CONFIGURATION OF CENTRAL FIELD

The possibility was also suggested that the configuration of the small central field present in these eyes at the beginning of this study might influence the eventual visual result in both the surgically and medically treated groups. The fields of all the eyes under consideration, although limited to those not greater than 10 degrees from fixation in all meridians, could be divided roughly into those which were round and those which were kidney-shaped. The latter configuration occurred in those eyes in which the nasal field was disproportionately constricted to fall within three degrees or less of the fixation point.

Among the 19 operated eyes, 9 fields were found to have been kidney-shaped in this way, preoperatively. Five of these eyes had visual acuities of better than 20/70, and 4 had vision reduced to 20/70 or less at the beginning of this study. Analysis of the effect of surgery on these eyes disclosed no significant difference in the incidence of reduced vision from that which occurred in the entire surgically treated group, either immediately after operation, or after the follow-up period. A reduction in visual acuity to less than 20/200 occurred in 44 percent of these eyes with kidney-shaped central fields; a result strikingly similar to the 47-percent incidence of such loss in the entire surgical group.

Among the 22 medically treated eyes, 8 presented kidney-shaped central fields as previously defined. Three of these eyes had visual acuities of better than 20/70, and 5 had vision of 20/70 or less. Under medical treatment that proved inadequate to control the tension, only 3 of these 8 eyes showed a further reduction in acuity during the follow-up period studied, and in only one instance did a loss of vision to less than 20/200 occur. The visual results in these eyes with kidney-shaped fields were, therefore, very similar to those which occurred in the medically treated group as a whole.

COMMENT

Although the number of eyes studied in each group is too small for detailed quantitative comparison of results, the grossly poorer visual status of the group of eyes that underwent surgery is striking. The immediate deleterious effect of operation on these very late cases of chronic simple glaucoma with telescopic fields is indicated by the early loss of some degree of acuity in 58 percent of these eyes. Over a follow-up period averaging over two years, this percentage of eyes with some visual loss postoperatively rose to 84 percent, and of the total number of operated eyes, 47 percent, or almost half, had suffered an extreme loss of vision to less than 20/200.

Contrasting results were presented by the

comparable group of eyes in which therapy was limited to miotic drops that proved inadequate to keep the tension within normal range. Of these, over a similar interval of time, 36 percent suffered some reduction in visual acuity, and in only 14 percent of this entire unoperated group was the loss of vision so severe as to reduce acuity to less than 20/200.

The reason for the unfavorable visual results following surgery in these cases is not clear. Certainly the restoration of normal tension to a glaucomatous eye would seem to be desirable in any stage of the disease. Nevertheless, in this series of cases of advanced glaucoma with marked field restriction, even operations that succeeded in controlling tension eventually resulted in a reduction in vision to less than 20/200 in 27 percent of the cases. In the 42 percent of cases in which operation failed to control tension, the incidence of such disabling loss in vision was 75 percent. In comparable eyes in which the tension was permitted to remain abnormally high by limiting therapy to local medication, such extreme loss was recorded in only 14 percent.

This suggests the possibility that, in advanced cases of chronic simple glaucoma, a functional equilibrium is attained that permits the retention of central vision in spite of abnormally high tensions over relatively long periods. Surgery apparently entails the hazard of disturbing this balance so that further loss of visual function is more likely to occur after operation even if the intraocular pressure is subsequently adequately controlled. When operation does not succeed in reducing ocular tension to normal range, as is common in these late cases, the disturbed functional balance plus continued tension elevation results in an extremely high incidence of severe visual loss.

Whatever the underlying cause may be, the facts here presented suggest that eyes with telescopic fields due to advanced glaucomatous damage tend to retain a useful degree of central vision for relatively long periods with simple medical treatment although tension may not be controlled. In such eyes, surgery employed to reduce the tension involves a significantly greater risk of incurring visual disability than does the continuation of apparently inadequate tension control through miotic therapy alone.

CONCLUSION

A study was made of the treatment of 41 eyes with uncontrolled chronic simple glaucoma sufficiently advanced to produce a constriction of central fields to 10 degrees from fixation.

In 19 of these eyes, surgery was performed to reduce the tension, with subsequent loss of some visual acuity in 84 percent of these cases, and a reduction in acuity to less than 20/200 in 47 percent, over a follow-up period averaging a little over two years.

In the remaining 22 eyes, the tension remained above normal range but no surgery was performed. In this group, over a comparable period, some visual loss occurred in 36 percent, and an extreme reduction in acuity to less than 20/200 in 14 percent.

These facts suggest that in eyes with advanced chronic simple glaucoma of this degree, central vision may be retained for long periods in spite of inadequately controlled tension, and that in such cases operation to reduce the tension is contraindicated.

CATARACT AND TETANY PRODUCED BY PARATHYROID DEFICIENCY DURING PREGNANCY, LACTATION, AND MENSTRUATION*

DONALD J. LYLE, M.D.
Cincinnati, Ohio

INTRODUCTION

Parathyroid deficiency may be classified according to its etiology into that produced by

1. Operative damage.

2. Intrinsic impairment from disease, or degeneration, or lack of development of the glands.

3. Extrinsic factors demanding immoderate function of the normal glands such as (a) Low calcium intake; (b) Depletion from conditions destroying calcium or demanding it in excess.

4. Not determined, unknown or idiopathic.

Last year was presented a case history and discussion of cataract and papilledema in parathyroid deficiency resulting from operative damage. This year I should like to present a case history of idiopathic parathyroid deficiency and discuss the effect upon it of pregnancy, lactation, and menstruation.

CASE REPORT

A white woman, aged 28 years, presented herself for examination because of failing vision in both eyes. Discrete opacities of various densities were found beneath the posterior capsule of both lenses, with a few raylike riders arching through the periphery to the anterior subcapsular area. This type of bilateral cataract in a young adult was immediately suggestive of endocrine disturbance.

The history prior to the beginning of diminished vision was irrelevant. There were no illnesses of severe nature, no operations, and the family history was entirely without

pertinent disclosure. The loss of sight began gradually during the first pregnancy and increased with lactation and a subsequent pregnancy. Finally, with menstruation, the vision became more disturbed.

Positive Chvostek's and Trousseau's signs and a low serum calcium of 7 mg. per 100 cc. of blood established the diagnosis of idiopathic parathyroid deficiency. The patient was sent for further laboratory tests and X-ray studies and was given a note to her physician stating the diagnosis and suggested treatment. She was asked to furnish a brief account regarding the onset and development of her symptoms. The following is from her letter:

"This eye condition started in the spring of 1943, shortly after I became pregnant. It was more noticeable when I tried to read. I nursed my first child for seven months and during that time noticed that the vision in my left eye was quite blurred. An eye doctor was consulted and he prescribed tinted lenses. To my recollection I noticed nothing until a month after I became pregnant with my second child, in December, 1945. The vision becoming worse, I consulted another doctor who told me I had an opacity in the back of my left lens, which might get better or worse. My sight became progressively worse with each month of pregnancy, although I could still read without much strain.

"As I look back on it now, with both pregnancies I was extremely nervous and despondent, with a constant twitching of the muscles of my hands and feet and one muscle in my stomach. I suffered with many leg cramps and rheumatism.

"I nursed my second child for four months until I noticed an increasing difficulty in reading. I then went to another doctor, who

told me I had cataracts in both eyes. I immediately stopped nursing (the last of November, 1946) and had a complete physical examination. A parathyroid deficiency was revealed and I was put on a low-phosphorus diet, calcium chloride, and vitamin D.

"My eye condition seemed to remain stationary until May, 1947, when in two weeks' time the eyes became much worse, particularly the better right one. I became sick at my stomach and saw heavy black spots and wave vibrations before my eyes.

"I now notice that during menstrual periods my vision is much worse, when I also am highly nervous and twitching · returns with a tingling sensation in my fingers and feet at night. The muscles of one eye also twitch. My sight definitely is weaker during the week of menstruation."

From this personal account there is very little doubt that this patient had an idiopathic hypoparathyroidism as manifested by the cataracts and tetanic muscular spasms.

As there was no history of any disturbance before her first pregnancy, we must conclude that the idiopathic deficiency which existed at a latent asymptomatic level was increased and aggravated by the pregnancies and periods of lactation and subsequently even by menstruation, to the manifest symptomatic level.

HISTORY AND ETIOLOGY

Relatively few cases of idiopathic hypoparathyroidism or spontaneous parathyroid insufficiency have been described. Two hundred and forty cases of tetany in pregnancy have been reported to 1942, and have been reviewed by Anderson and Musselman.[1] Possibly three additional cases have been reported since then. Of this series, beginning with the report of a case in 1830, 146 were classified as idiopathic, which included those produced by pregnancy and lactation. The report of the presence of cataracts was infrequent. There is no doubt that lenticular changes were present in more cases, and would have been revealed had they been looked for or had better equipment for examination been available. Of still less frequency was the report of the presence of optic neuritis. Postoperative conditions, thyroid deficiency, and dietary lack of calcium and vitamin D comprise the remaining classifications.

The cause of idiopathic hypoparathyroidism is not well understood. It may be the result of an arrest in the growth of the glands, their pathologic destruction, or their degeneration after they have normally developed. They should receive a different and definite classification with the advent of additional knowledge. This loss, from whatever cause, implies, of course, the inability to produce the activating substance, the parathormone, whose chief action appears to be the maintenance of normal blood-serum levels of calcium and phosphorus. Other factors influencing the blood calcium level are the intake of calcium and phosphorus, the presence of vitamin D, the alkalinity or acidity of the ingested food, and the body tissues, and the pH of the blood.

The presence of parathormone increases the calcium level of the blood, as does a slightly acid state. The presence of phosphorus decreases the calcium level in direct ratio. The ingestion of calcium and phosphorus increases the amount of calcium and phosphorus available to the blood and tissues, the excess being excreted. Vitamin D is essential to normal absorption, utilization, and excretion of calcium, helping to maintain a constant normal blood level.

Ninety-nine percent of the calcium in the body is in the skeletal system, which, excepting the mature teeth, is labile and capable of being released back into the circulation. Calcium is found in all of the secretions and excretions of the body, especially in the feces. The regulation and maintenance of a relatively constant level of calcium in the blood depends upon the balance between the calcium intake, utilization, and excretion.

In the latent form of hypoparathyroidism with its accompanying reduced level of

serum calcium, equilibrium is maintained, with a narrow margin of safety, in an asymptomatic course. However, with the advent of pregnancy and lactation, the narrow margin of calcium reserve is reduced by depletion through fetal skeletal and lactogenic needs to the symptomatic level of manifest hypoparathyroidism. Because the previous serum calcium level is never reached after each pregnancy and lactation, subsequent menstruation may sufficiently deplete the reserve to bring about periodically the return of the symptoms.

During early pregnancy, the slight fetal demand for calcium results in no reduction in the maternal blood calcium level, unless there has been an inadequate intake in the diet or unless there is a deficiency in other factors conducive to maintaining a normal level such as is found in parathyroid deficiency. Normally, the necessary increase at this time is adequately provided by the stored calcium. During late pregnancy there occurs a reduction of maternal serum calcium, variously reported as from very little to 0.5 to 1 mg. percent below the previous level. This reduction is produced notwithstanding a hypertrophy of the parathyroid glands in a compensatory effort and the acquisition of a property in the blood of the pregnant woman, similar to that of parathormone, which increases the calcium serum level.

Whether this calcium reduction is still further produced by an altered parathyroid function or is the result of the influence of other endocrine glands which have been activated by the existing condition is at present conjectural. It has also been suggested that the placenta may produce a depressing agent which may influence the calcium level.

Thus, in pregnancy, lactation, and menstruation, it appears that, in addition to the somewhat variable calcium intake, not only the stored but the circulating calcium is called upon to meet the drain for fetal needs and for the production of milk and menstrual loss. When the level of serum calcium is lowered too far, symptoms of neuromuscular irritability and ectodermal trophic disturbance appear.

SYMPTOMS

The chief symptoms of hypoparathyroidism are included under the designation of tetany. The symptoms produced by tetany are common to all types alike. In order of their usual appearance and severity they are:

1. Tingling or paresthesia of the hands, feet, and face.
2. Carpópedal contraction.
3. Contraction of the abdominal muscles.
4. Laryngospasm.
5. Generalized convulsion.

The first three symptoms were found in the patient reported in this paper; the last two in the previously reported case.[11]

Vague or accompanying symptoms are:

1. Fatigue and musclar weakness.
2. Gastrointestinal irritability.
3. General nervous irritability.
4. Mental retardation.
5. Polyneuritis, which includes optic neuritis.

Most of the above symptoms are produced by irritation of the neuro-ectodermal system, chiefly as a result of the nervous excitability produced by a decrease in calcium acting upon the neuromuscular juncture as the contraction is arrested by the administration of curare.

Once more the question arises concerning the type and cause of change in the neural structures accompanying and producing visual loss in tetany. In a previous paper,[11] this condition was reported as possibly a papilledema and cerebral edema, although the marked and early loss of vision was more suggestive of optic neuritis. This condition again introduces itself, appearing during the menstruation in the patient whose case is presented in this paper. She complained of disturbed and diminished vision during her menstrual periods, which was in addition to the gradual loss of sight from her develop-

ing cataracts. Unfortunately, her lenticular opacities prevented a definite view of the papilla.

Papillitis and retrobulbar neuritis associated with pregnancy, lactation, and menstruation have been reported in the literature on rare occasions. The most recent reference found was by Lillie,[10] who described a "marked acute optic neuritis and swelling of the disc 2 to 3 diopters," with complete blindness, in a woman who nursed her third child for 2½ months. So far as can be determined, no laboratory tests were made in any of the reported cases, and no pathologic material was studied. No adequate discussion as to the probable primary cause was presented. It was stated that "the cause of such a neuritis is obscure." Some suggested[6] multiple sclerosis, metabolic, or toxic causes.

If one considers the general subject of polyneuritis, he finds that there is a remarkable similarity between the symptoms produced by this comprehensive nerve involvement and those found in tetany. In both polyneuritis and tetany the sensory, motor, and general symptoms, such as fatigue and mental deterioration, are alike. Restricting the polyneuritis to the cranial nerves, the so-called polyneuritis cranialis, the facial, oculomotor, and vagus are most frequently involved; the optic nerve rarely. These nerves are also involved in the same order in tetany. The literature gives a few sentences to relapsing recurring polyneuritis, and states that this classification includes the cases found in pregnancy and the puerperium. There is the suggestion that the repeated attacks during subsequent pregnancies are due to identical circumstances or minores resistentiae.[15]

Although I do not infer that all polyneuritis has a low blood calcium with tetany, it seems to me very likely that the optic neuritis found in these women during pregnancy, lactation, and menstruation is a type of aseptic polyneuritis which is induced by low calcium level. This polyneuritis, which also affects the central nervous system, may produce an interstitial edema and venous engorgement, with cellular infiltrates and exudates. It also may produce a wallerian degeneration of the axons with demyelinization and neuronal swelling, granulation, fragmentation, and necrosis. It is reasonable to assume that the edema or aseptic inflammation of the visual system occurring in tetany accompanying parathyroid deficiency is the result of the tissue changes produced by calcium deficiency with its concurrent metabolic disturbances and functional loss.

In addition to the neuro-ectodermal affections, changes also occur in the somatic ectodermal tissue, resulting in loss of hair, nails, dental arrest in childhood, and cataract formation.

Hypoparathyroid tetany may be differentiated from other causes by:

1. Reduced serum calcium below 8.5 mg. percent.

2. Normal or increased serum phosphorus above 4.5 mg. percent.

3. Decrease in urinary excretion of calcium and phosphorus.

4. Normal serum phosphatase.

5. Normal acid base equilibrium.

6. Absence of significant osseous changes as evidenced by X-ray findings.

7. Absence of renal insufficiency.*

TREATMENT

The necessity for various types of treat-

---

* A low blood calcium with tetany is also found in rickets in the child and osteomalacia in the adult, and in renal insufficiency. Low blood calcium without tetany is found in:
1. Hypoproteinemia whenever there is enough free calcium to produce symptoms of calcium deficiency.
2. Hyperphosphatemia of nephritis and uremia where phosphorus ratio is lower than the calcium level.
Tetany occurring with hypoparathyroidism is found in:
1. Nutritional disturbances with lack of vitamin D and calcium.
2. Depletion from exhausting diseases, poisons, and toxins.
3. Need for greater calcium than can be provided: (a) hyperventilation; (b) alkalosis; (c) Possibly pregnancy and lactation.

ment may be determined by testing the urine or blood. The Sulkowitch urine test for calcium should be made at frequent intervals. If the test reveals a milky precipitate, there is an overabundance of calcium and hypercalcemia is present. If the test reveals clear solution, no calcium is being excreted in the urine and the blood calcium is probably 7 mg. percent or less, the patient being

cium lactate in water 3 times daily is recommended. Ten cc. of 30-percent solution of calcium chloride 3 times a day after meals will also increase the acidity of the blood, which in turn will raise the calcium level. The calcium and phosphorus intake must be increased 10 to 20 percent in pregnancy, and much more in lactation. This means an average daily intake of 1.5 gm. of calcium in
Fig. 1 (Lyle). A schematic arrangement charting the fluctuation of the serum calcium level in a patient with idiopathic parathyroid deficiency during pregnancy, lactation, and menstruation.

in a state of hypocalcemia. If the test shows a slight clouding, the serum calcium is probably present in normal amounts. If the Sulkowitch test reveals a hypocalcemia, 3 cc. of dihydrotachysterol should be given daily until there is a clouding, and then 1 cc. 3 to 5 times a week as a maintenance dosage. For further check, a blood calcium test should be made at monthly intervals.

The purpose of treatment is to elevate the blood serum calcium content and diminish the phosphorus. Prophylactic medication begun at the fifth month of pregnancy, terminated at labor and resumed at the end of the first month of lactation should be advised. One teaspoonful of calcium gluconate or cal-

pregnancy and more in lactation. It may also be needed after pregnancy, as it must be remembered that the blood serum thereafter is pegged at a lower level. In addition to the increased calcium, the phosphorus and phosphate intake should be restricted. Dihydrotachysterol and vitamin D should be given.

Dietary restrictions and needs should be considered. Dairy products, meats, legumes, potatoes and whole wheat cereals should be restricted or curtailed. One must remember that although milk contains an abundance of calcium, it also contains an abundance of phosphorus, which unites with the calcium to form an insoluble calcium phosphate which at least partially nullifies the benefit of the

calcium. Foods which may be approved are fruits, vegetables, fats, and carbohydrates.

If tetany appears, and with it the probability of cataract and optic-nerve involvement, active treatment is necessary to raise the blood calcium level immediately. In the acute state, inhalation of 5 to 10-percent carbon dioxide in air or oxygen will reduce the alkalinity of the blood and raise the calcium concentration. Ammonium chloride by mouth will have a similar effect. Sedatives to relieve the tetanic spasms of contraction may be necessary. Chloral hydrate, barbitals, or demerol may be of use for this purpose. Magnesium salts in various forms of administration may be employed to reduce the irritability and swelling. Calicum salts employed in a like manner may have an immediate effect of short duration. Ten to 20 cc. of 10-percent calcium gluconate may be administered intravenously and 25 to 30 gm. of calcium lactate may be given in warm water orally.

In the chronic state, the treatment, aside from dietary aids, is the administration of calcium in various forms, parathyroid hormone, vitamin D, and dihydrotachysterol.

SUMMARY

A case history of a patient having idiopathic parathyroid insufficiency was presented to introduce the subject (fig. 1). Her developing symptoms produced by cataract and tetany were described as she passed through pregnancy, lactation, and menstruation. A brief history of spontaneous or idiopathic hypoparathyroidism was presented. Possible causes of its production were mentioned. The sources, use and disposition of calcium to meet the body needs were described, and factors influencing its activity were enumerated. The changes produced by pregnancy, lactation, and menstruation were discussed, and the symptoms resulting from the additional presence of hypoparathyroid insufficiency were described and a differential diagnosis was outlined.

Treatment was recommended for prevention and for the latent and manifest stages of parathyroidism.

CONCLUSION

The increased demand for calcium during pregnancy, lactation, and menstruation may change an asymptomatic latent parathyroid deficiency into a symptomatic manifest hypoparathyroidism, with serious consequences to vision through ectodermal damage, both neural and somatic. These complications can be averted by routine examination during early pregnancy and lactation. Treatment, once the symptoms have appeared, may arrest but cannot entirely restore the visual loss.

ETIOLOGY OF TRACHOMA*

YUKIHIKO MITSUI,† M.D.
Kumamoto, Japan

This article is based on a series of investigations performed under the guidance of Prof. Shinobu Ishihara and Prof. Takeo Tamiya at Tokyo University. A total of 105 human inoculation experiments were performed, in cases hopelessly blind from other causes. The results have been published in a Japanese monograph.[21]

1. Adult inoculation with trachoma.[1-3] Material from cases of the late chronic stage of trachoma but with typical, confluent, turbid follicles was inoculated in 31 cases, with 26 positive results. The inoculum, obtained by scraping the follicles at the superior border of the tarsal conjunctiva with a knife, was rubbed into the conjunctival surface. The only aseptic precautions were an irrigation with sterile boric acid solution and the usual sterile procedures. In positive cases the incubation period was 3 to 9 days with an average of 5 to 6 days. The initial stage was always an acute conjunctivitis and, in all cases, follicles appeared within a few days. After several days, there was a full-blown acute follicular conjunctivitis. Acute inflammation reached its climax within a month, then began to subside, and within 1 to 3 months gradually went over to the chronic form. Prowazek-Halberstaedter inclusion bodies were found without exception.

In the majority of the cases, the signs of chronic follicular conjunctivitis were persistent. Examination even after 1 or 2 years revealed the typical signs. Perfect cure within several months was the exception. In 18 cases the disease went over to the second eye spontaneously. The symptoms and course were almost the same as those in the inoculated eye. Prowazek-Halberstaedter inclusion bodies were also found without

exception. Their numbers were in proportion to the severity of the clinical symptoms.

ETIOLOGIC NATURE OF PROWAZEK-HALBERSTAEDTER INCLUSION BODIES

A. DEMONSTRATING THE BODIES IN CHRONIC TRACHOMA

The first object was to establish a positive identification of the inclusion bodies, when present, in chronic cases, because it has been commonly believed that the Prowazek inclusion bodies cannot be readily demonstrated in the chronic stages of trachoma.

The following total of 823 cases were studied in order to clarify this point: (1) A preliminary study of 290 cases in the ophthalmology department of Tokyo University;[4] (2) A farmer's village, Naruse, Kanagawa Prefecture, 175 cases[6]; (3) A fisherman's village, Shinojima Island, Aichi Prefecture, 156 cases[7]; (4) A special series in the ophthalmology department of Tokyo University, 202 successive cases.[8]

Prowazek-Halberstaedter bodies were found in 537 (65 percent) of the 823 cases. These 823 cases consisted of both typical and suspected cases. Among 392 cases with typical clinical symptoms, 336 (85 percent) were positive for the inclusion bodies. The results are summarized in Table 1.

The percentage of positive findings, as well as the number of Prowazek-Halberstaedter bodies counted, paralleled the development of the follicles, that is, it followed the number, turbidity, and confluence of the follicles, and hence was more dependent on the presence of such follicles than it was on the early or late stages of infection.

This is in contrast with the conclusion, from unselected cases, that the finding of inclusion bodies decreases with increasing chronicity (table 1, column 1). If the advanced cases are selected according to typical

1189

follicle formation, and. the increasing pro-
portion of latent or doubtful cases are ex-
cluded, then there is only a small decrease of
percentage of cases positive for inclusion
bodies, as can be seen from the last three
columns of Table 1. Instead of 100-percent
findings of inclusion bodies, as occurred with
47 acute cases from the same districts, the
incidence of inclusion bodies in these
chronic cases with typical folliculitis was
of the order of 80 to 90 percent.

The question arises why even this small

the lesions by irrigation or other treatment.
The inclusion bodies were found in the
uppermost epithelial layers of those follicles
which had become turbid and confluent.
Scrapings were collected exclusively from
such regions, which occurred chiefly in the
conjunctiva of the upper fornix. Trans-
lucent, not confluent, follicles yielded few
inclusion bodies; papillas and cicatrix almost
none.

The conjunctival sac was anesthetized
by instillation, without irrigation, of 2-per-

TABLE 1

PERCENTAGE OF TYPICAL CASES OF TRACHOMA WITH PROWAZEK-HALBERSTAEDTER BODIES

Stage of Infection	Prowazek Bodies	Tokyo University, 1938		Prowazek Bodies Special Series		
		Percent Cases:		Naruse Village	Shinojima	Tokyo Univ. 1939
		Typical	Severe			
Acute	100	100	100	100	100	100
Chronic:						
Stage 1	59	73	25	81	76	82
Stage 2	54	60	4.4	87	83	87
Stage 3	37	50	0.8	74	100	96

Chronic Stage 1 is classified as an early stage without cicatrix.
Chronic Stage 2 is an advanced stage with superficial cicatrix but without complications due to cicatricial shrinkage.
Chronic Stage 3 is the late stage with thick, deep cicatrix and complications due to cicatricial shrinkage, such as trichiasis or entropion.
A typical case is a case with follicles which are turbid and confluent.
A severe case is a typical case in which the follicles are rich in number, markedly turbid and markedly confluent. It does not include the chronic cases wherein the appearance of severity is due to secondary changes dependent upon entropion, ectropion, blepharophimosis, or pannus formation.

decrease from 100 percent should occur. The
answer is simple. In the acute stage, the
follicular inflammation is not only typical
but also severe. Conversely, in chronic stages
the frequency of severe follicular inflamma-
tion decreases, as the conversion to milder
cases increases, even though the milder cases
may be still classified as typical (table 1,
column 2). It can be said that there is no
real trachoma without Prowazek-Halber-
staedter inclusion bodies.

The many reports asserting a marked les-
sening of positive findings in chronic stages
may be the result of technical differences
such as different procedures and classifi-
cations.

Technique. It was important not to disturb

cent cocaine. Turbid, confluent follicles were
scraped with a cover glass, taking care not to
rupture the follicles or cause hemorrhage.
The smear, spread as in the method of blood
smears, was then fixed with methyl alcohol
and stained. The most suitable staining was
obtained with 2 to 3 drops of Giemsa stain
(Grübler, prepared in carbon-dioxide free
distilled water; other brands were unsuit-
able) in 2 cc. of distilled water for 30 to 60
minutes at room temperature. More rapid
staining, adequate for diagnosis, can be ob-
tained by using 5 to 10 drops of stain in 2
cc. of the carbon-dioxide free distilled water.
The inclusion bodies are best located with a
magnification of 40 or 80 times, and then
studied under oil immersion.

B. Histologic investigation of inclusion bodies[5]

Tissue sections were positive for Prowazek-Halberstaedter bodies in 92 percent or 108 of 117 cases. The inclusion bodies were in the epithelial cells at the tops of the follicles. Inclusion bodies were never found in the subepithelial tissues; they were in epithelial cells only. It has been a question for some time, how they can occur only in this site if they are the infecting agent, and why they cannot be found in the follicles themselves, which are the site of the most significant changes in trachoma. Theoretically, it may be unnecessary to prove the existence of the virus in the follicle, since a toxic substance, elicited or elaborated by the virus, may cause the follicles.

Investigations were performed to determine whether the locus of the virus is identical with the histologic site of the inclusion bodies.

C. Absence of trachoma virus in subconjunctival tissues[9]

Ten cases of typical trachoma, trachoma with turbid and confluent follicles, in various stages, all Prowazek inclusion-body positive, were selected as donors. Subconjunctival tissue, usually from the tarsal tissue as indicated in Figure 1-a, was taken in order to avoid touching the conjunctival epithelium. The tissues were ground in Tyrode's solution so as to make an emulsion. Ten eyes of 6 patients were inoculated by dropping the emulsion into the conjunctivas and massaging. These recipients were blind from intraocular diseases, such as optic-nerve atrophy and absolute glaucoma, but were free of trachoma. The results were all negative.

Two control inoculations into 2 eyes were both positive; they reacted with a typical trachoma, and were positive for inclusion bodies. The inoculum for these controls was prepared in the same manner as above, except that the starting material was obtained as scrapings from the conjunctival epithelium

of the upper tarsus as in Figure 1-b from 2 of the same donors.

A second investigation was designed to determine if subconjunctival inoculation would result in trachoma.[10] The inoculum from conjunctival trachoma epithelium scrapings was prepared as before. It was in-
Fig. 1 (Mitsui). (a) Tarsal plate tissue of a typical trachomatous case was removed surgically from the cutaneous side, and inoculated with negative result. (b) Scrapings from the tarsal conjunctiva of the same case were inoculated with positive result.

jected, from the cutaneous side as in Figure 2-a, subconjunctivally into the region of the retrotarsal fold. Ten such inoculations were performed. They all remained negative for trachoma. A control instillation of the same inoculum into a conjunctival sac was positive, as in Figure 2-b. Absence of pathogenic bacterial contamination was demonstrated by culture and subsequent control inoculation of these cultures into human eyes.

From these results, it is concluded that (1) The trachoma virus exists only in the epithelial layer, not in the subconjunctival tissues; (2) the trachoma virus cannot cause trachoma when it is introduced into the subconjunctival tissues only, without touching the epithelium. It may be said that the tra-

choma virus and the Prowazek-Halber-staedter inclusion bodies are at the same locus, regardless of whether or not the inclusion bodies are the actual infectious agent.

D. PROVOCATIVE TESTS[11]

In the above investigations, it was easier to demonstrate the inclusion bodies in the
Fig. 2. (Mitsui) (a) Suspension of scrapings from typical trachoma cases was injected sub-conjunctivally from the cutaneous side. It could not start trachoma. (b) The same inoculum was dropped into the conjunctival sac. The trachoma started.

cases with the more severe folliculitis. Similarly the ease of demonstrating inclusion bodies lessens with the decrease of number, turbidity, and confluence of the follicles, during and after treatment.

To investigate the converse, whether the ease of demonstrating inclusion bodies increases, in the individual case, with exacerbation of the typical folliculitis, a method for provocation of the disease was utilized. The conjunctivas were scraped with the edge of a knife or rubbed with cotton. Then, without

irrigation, a bandage was placed over the eye. In 8 of 15 cases, the severity of the folliculitis was reached within 5 to 10 days and, at the same time, the number of inclusion bodies increased.

The inclusion bodies, on the whole, were smaller in the acute stages of the exacerbations, which also occurs in the acute stages of the spontaneous infection. But, when the typical follicular lesion in the provocative test increased gradually, the frequency of the larger cells, containing elementary bodies, increased also, just as in slowly progressing spontaneous trachoma.

E. PURE CULTURE OF PROWAZEK-HALBER-STAEDTER BODIES

The conjunctival sac was first thoroughly irrigated with sterile saline solution. A strip of conjunctival tissue with marked follicle formation was removed surgically and cut into 1 by 1 mm.-sized pieces in Tyrode's solution.

The sterile culture medium was made up of two stock portions: (a) Human blood plasma, 1 part, chicken blood plasma, 2 parts; and Tyrode's solution 10 to 30 parts. (b) Juice of chicken embryo. At the time of culturing, the stocks a and b were mixed in the ratio of 2:3 or of 3:5.

The epithelium grew by cell division. Inclusion bodies were found also in what appeared to be new cells.

In second generation subculturing, the above tissue cultures were ground to a suspension and diluted 10 times in Tyrode's solution. Tissue from normal conjunctivas was carried through this suspension and then cultured as above.

Smears of the cultures, at 2 to 5 days, were stained and examined. By comparison with the original tissue, the number of cells with inclusion bodies increased, as did also their size, with elementary bodies filling almost the entire cytoplasm. Of 2 cases with too few inclusion bodies to demonstrate initially, inclusion bodies could be demonstrated from the culture in 1 case. Cultivated

tissue introduced into the human eye in 4 cases, resulted in trachoma each time. Such inoculations from subcultures, however, were not successful. Hence, although these cultures suggest that the infectious agent has been cultured, they do not prove this conclusively.

RELATIONSHIP BETWEEN TRACHOMA AND INCLUSION BLENNORRHEA

Inclusion blennorrhea of the newborn was studied in 18 cases.[14, 15] This provided a basis for comparison.

Inoculations of suspensions from tracho-

The converse inoculation, from the conjunctivas of newborn children with inclusion blennorrhea into adult conjunctivas, was performed in 10 eyes[16] of 10 adults. The resulting disease in the adult was identical with inoculated trachoma of the adult,[1-3] but not with inclusion blennorrhea of the newborn.

To exclude possible individual variation, the 2 inoculations (trachoma inoculum and blennorrhea inoculum) into the 2 eyes of the same individual were performed in 7 cases. No essential difference between the two eyes was observed;[17] all exhibited the trachoma-
Fig. 3 (Mitsui). Trachoma follicles of the inclusion blennorrhea type.

matous scrapings were instilled into the conjunctival sacs of four eyes of four newborn children, blind from congenital anomalies such as microphthalmos and corneal degeneration but not having trachoma, at 5 to 29 days after birth. The response, a blennorrhea or pseudomembranous conjunctivitis, was followed clinically.

Follicles were not found until the babies became several months old, but these follicles were somewhat different from those of adults, just as those of spontaneous inclusion blennorrhea are different. They formed deep in the areolar connective tissue layer, as indicated in Figure 3, instead of the adenoid tissue, as in the adult trachoma (fig. 4). They had a "naked" appearance, that is, with little or no wall of lymphocytes (fig. 4).

Trachoma in the newborn is, therefore, quite different than that of the adult, but identical with the inclusion blennorrhea of the newborn, both clinically and microscopically.

tous type of infection.

Tissue sections of the cervical canals, but not of the vaginas, of mothers of babies with inclusion blennorrhea, had microscopic changes similar to those of conjunctival trachoma.[18] Prowazek-Halberstaedter inclusion bodies in the cervical scrapings were found in one case. Instillation of inoculums prepared from cervical canal scrapings, pre-
Fig. 4 (Mitsui). Trachoma follicles of the adenoid or adult type.

pared from 6 cases, into 6 adult eyes of 6 people resulted in typical trachoma.

The converse experiment,[19] inoculation of the female genital tract with trachomatous materials, produced the typical infection of the cervical canal as manifested by microscopic changes. In the cases of the 2 women so inoculated, continued presence of the infectious agent was demonstrated 14 days later, by a further inoculation into other adult eyes. Gynecologic examination 7 months after inoculation in 1 of the women demonstrated that there were clinical and microscopic findings of genital trachoma, including follicle formation, cellular infiltration, and numerous inclusion bodies, in tissue sections of cervical-canal epithelium.

No doubt can remain that trachoma and inclusion blennorrhea are results of the same infection. Inclusion blennorrhea is infant trachoma. Furthermore, trachoma is not exclusively an eye disease, but can alternate between the eye and the female genital tract. It may be assumed that the disease of the female genital tract is the usual source of infection during delivery, resulting in inclusion blennorrhea of the newborn.

TRACHOMA IN THE LACRIMAL APPARATUS[12]

It is well known that trachoma follicles are most readily found in the tarsal conjunctiva, or in the conjunctiva of the retrotarsal fold. These are loci of cylindrical epithelium, the epithelium of the fold being the more typically cylindrical. The cuboidally flattened epithelium of the bulbar conjunctiva or the squamous epithelium of the cornea are hardly affected by trachoma, except secondarily. Likewise, the genital tract trachoma showed that the cylindrical epithelium of the cervical canal could be easily infected, but the stratified squamous epithelium of the vagina could not.

The cylindrical epithelium of the lacrimal sac was also found to be affected by trachoma.

A suspension of trachoma material was injected with a lacrimal syringe into 6 lacrimal sacs through the inferior punctum. The sacs were removed 10 to 51 days after inoculation and were examined histologically. The changes were identical to those of trachoma of the conjunctiva. Inclusion bodies were demonstrated in 5 cases.

The lacrimal sacs were removed from 6 cases of early conjunctival trachoma; 1 of these had been experimentally inoculated, 1 was in the acute stage, and 4 were in an early chronic stage of infection. Histologic changes in the sacs were almost identical to those of the conjunctiva. Inclusion bodies were found in 5 of them. In 2 cases, the canaliculi were examined. Inflammatory changes consisting of round-cell infiltrations and follicle formations were slight, as compared with those of the sacs, yet inclusion bodies were present in the epithelium of each.

The lacrimal sac was examined in 1 case of conjunctival trachoma induced by inoculation from a case of inclusion blennorrhea. Changes were like those of spontaneous trachoma and many inclusion bodies were present.

Lacrimal sacs were also studied in 13 cases of chronic conjunctival trachoma. Follicle formation and cellular infiltration were slight as compared with the conjunctivas of the same cases; cicatricial changes were marked. In some cases, the resulting constriction had reduced the lumen of the sac greatly. Inclusion bodies were found in one case.

In nonspecific, chronic dacryocystitis, unaccompanied by trachoma, the inflammation was not specific and no inclusion bodies were found.

CLINICAL COURSE OF TRACHOMA

A. INITIAL ACUTE STAGE

Formerly, it was believed that trachoma starts insidiously, and so-called acute trachoma was thought to be only an exception. It was known that an inoculated trachoma started acutely, but this was considered to

be a special response to inoculation, such as might result from an infection with enormous numbers of virus at one time. For reasons to be summarized, it is concluded that without exception trachoma starts acutely and that the incubation period is 3 to 9 days, usually 5 to 6 days.

Inoculation trachoma, in 68 cases,[1, 9, 10, 13, 15-19] started acutely without exception. The incubation period was slightly shorter with larger doses of inoculum, and the folliculitis somewhat less acute.[17] Not only was the onset of the inoculated trachoma acute, but so also was that which went over spontaneously to the second eye, 21 cases.[1, 15, 16, 18] In none of these cases, whether by inoculatio nor by spontaneous spread to the second eye, did the trachoma start insidiously.

Acute trachoma is not a rare occurrence. In 6 months, 44 cases were seen in Tokyo University.[8] Meanwhile, 202 cases of chronic stages were observed. Of the 44 acute cases, the great majority had received prior treatment from their local ophthalmologists for what was evidently considered to be a simple follicular conjunctivitis rather than an acute trachoma.

Thirty-three patients,[8] with trachoma in the early chronic stage, gave a history of an acute conjunctivitis originating 1 or 2 years previously, starting in one eye and being followed 7 to 14 days later by a similar onset in the second eye. This long delay is consistent with the incubation period of trachoma, as contrasted with the rapid onset of a bacterial conjunctivitis, signs of which were lacking. The subjective symptoms had subsided slowly. Their local ophthalmologists had told them that they had an acute conjunctivitis; those who had been told that they had an acute trachoma were the exception.

Another reason for the persistent belief that an acute trachoma is the exceptional form of trachoma arises from the apparently benign nature of the disease. The cicatrix and pannus do not occur until several years later.

Still another reason that trachoma has

been easily overlooked in its acute stage, is evident from the statistical investigations in Naruse[6] and Shinojima,[7] where the initial affection of trachoma occurs in childhood, usually before 3 or 4 years of age. It is evident that, through the lack of an active complaint from the patients, any acute conjunctivitis in childhood may be considered and treated lightly. Hence the tendency to overlook trachoma of the acute stage. In regions of high trachomatous incidence, it may be presumed that acute trachoma should be a childhood disease.

This is supported by the relation of the percentage incidence of all stages of trachoma with respect to age, in the villages of Naruse and Shinojima. The incidence approached was 17 percent and 75 percent respectively. These levels were already approached at the school age and remained practically constant thereafter, although the trachoma progressed to more advanced stages of the disease in the advanced age groups.

B. INTERVAL FOR CHRONIC TRACHOMA

Analysis of cases of trachoma in Naruse and Shinojima indicated the following: Chronic trachoma occurring in young people is of the first-stage type, without cicatrix, in the majority of cases; in middle aged people, it is usually of the second-stage type, superficial cicatrix without complications; and the third stage, cicatricial retraction and complications, is almost exclusively observed among people over 40 or 50 years of age. This indicates that trachoma may persist for a long time, perhaps 10 or 20 years or more, after the acute stage and before formation of cicatrix; perhaps 40 to 50 years before cicatricial retraction and complications.

C. HEALING OF ACUTE TRACHOMA

It is known that numerous cases of early trachoma can be cured without leaving any trace. The earlier the improvement the more likely the cure. It is, therefore, a most important problem from the standpoint of pub-

lic health that trachoma be detected in the early stage. For this, examination for inclusion bodies is indispensable.

The procedure utilized and discussed herein for recognition of suspected, suspicious, typical, and atypical cases should become familiar to all ophthalmologists in routine examination of ocular infections.

THE DUPUY-DUTEMPS DACRYOCYSTORHINOSTOMY*

ALTON V. HALLUM, M.D.
Atlanta, Georgia

Dacryocystorhinostomy has proved to be so highly successful in the hands of many surgeons that extirpation of an obstructed lacrimal sac has come to be supplanted by it, just as couching long ago was supplanted by cataract extraction. Another surgical analogy of extirpation versus dacryocystorhinostomy might be made of the orthopedic surgeon who would elect to amputate a patient's broken leg, rather than go to the trouble and time to help restore the function of the leg. The extirpation of obstructed lacrimal sacs is usually successful in relieving the pus and mucus, but the majority of the patients are doomed to a life of lacrimation and its annoying impairment of vision. A correctly performed dacryocystorhinostomy in selected cases can be expected to relieve completely pus, mucus, and tearing in at least 95 percent of the cases.

HISTORICAL REVIEW

The reader is referred to Chandler's[1] discussion on this subject in which he reports an exhaustive survey of the literature. According to Chandler, history shows that operations were performed by Celsus, to make a new passageway from the tear sac into the nose as long ago as the first century and by Galen in the second century. In modern times, in the early 18th century, Woolhouse and Platner performed operations to reestablish drainage of the lacrimal sac into the nose. The procedure was apparently forgotten or abandoned for approximately two centuries.

In 1904, Speciale-Cirincione[2] and Toti,[3] in Italy, revived the operation, each with a different technique. Speciale-Cirincione's

transplantation operation consisted of lifting the sac from its bed and pushing the lower end of the sac into the nose through a new bony opening. The transplantation operation is applicable only to those cases where the obstruction is limited to the lower end of the lacrimal sac and nasolacrimal duct.

Forsmark,[4] Stokes,[5] Gifford,[6] and others have reported highly successful series of operations using the transplantation method. Toti advocated removing the nasal wall of the lacrimal sac and a corresponding area of the underlying lacrimal and maxillary bone and muscosa, thereby reestablishing drainage from the lacrimal sac into the nasal cavity.

Many variations in the technique of Toti have been made by different surgeons. In 1912, Blascovicz[7] made the first significant change by cutting away all of the sac wall except a small portion immediately surrounding the opening of the canaliculi. In 1914, Kuhnt[8] was probably the first to approximate the mucous membranes by sutures. Ohm,[9] in 1920, advised making vertical incisions in the nasal mucosa and lacrimal sac wall and then suturing the respective posterior flaps and anterior flaps.

In 1921 Mosher[10] described a modification of Toti's technique. He advocated (1) exenterating the ethmoid cells in the vicinity of the lacrimal sac, (2) resecting the nasal mucosa from the bony window, (3) resecting the inner wall of the sac and duct down to the upper rim of the inferior turbinate, and (4) removing the anterior tip of the middle turbinate.

In an address in 1937, as guest of honor of the American Academy of Ophthalmology and Otolaryngology, Mosher[11] stated the operation should be successful in 90 percent of the cases if properly performed. He also said that in his opinion a high deviation of

the nasal septum should be previously straightened, to prevent blocking of the new opening. The technique as outlined by Mosher requires that the surgeon be an experienced rhinologist.

Also in 1920-1922, Dupuy-Dutemps and Bourguet[12] described a modification of Toti's technique, similar to Ohm's, which was much simpler than Mosher's, and required no intranasal surgery. They reported more than 1,000 operations in which 94 percent had been successful. During recent years, Chandler,[1] Rychener,[13] Yanes,[14] Hughes, Guy, and Bogart,[15] Hallum,[16] and others have reported series of operations using the technique popularly known as that of Dupuy-Dutemps. Each of the surgeons has reported successful results in nearly all of the cases, Chandler and Rychener in 100 percent of the cases. Chandler prefers to make T incisions instead of I incisions in the sac wall and nasal mucosa.

Traquair[17] reported 409 operations by the technique of Toti and a follow-up on 321 of the patients found that 80 percent of them had been relieved of watering. He altered the technique of Toti by suturing a flap of nasal mucosa to the anterior margin of the lateral sac wall after he had removed the inner wall of the sac. Thus his technique was very similar to that of Ohm and Dupuy-Dutemps.

Hogan[18] recently reported a series of 49 Toti-Mosher operations done at the University of California over a 20-year period, including the cases formerly reported by Martin and Cordes[19] and Martin.[20] These surgeons feel that the operation as done by them should be successful in 85 to 90 percent of the cases.

The postoperative care necessary to prevent granulation tissue from blocking the new passageway is a great task for the surgeon, and is one of the greatest shortcomings of this procedure. They perform postoperative irrigation of the lower punctum daily for the first week, then twice weekly for a month, and thereafter at monthly intervals.

ETIOLOGY OF OBSTRUCTION OF THE NASOLACRIMAL PASSAGEWAY

When this subject is discussed by rhinologists[21] some of them say that as high as 95 percent is of nasal origin. But when discussed from the standpoint of the ophthalmologist, it appears that the nose plays a relatively insignificant role in producing infection in the lacrimal sac. In Traquair's 409 cases he found only one with any obvious intranasal pathology. This patient had a few small polypi in the middle meatus, which were removed during the operation.

Most patients are unable to associate the onset of the epiphora and pus with any acute nose or lid infection. Trauma was the predisposing factor in 4 or 5 percent of most series, but in my series it was the cause in 17 percent. The most constant factor in most series is that the great majority of patients are women. The percentage of women was 80 in Traquair's series, 66 in Gifford's series, and 58 in my series. As Traquair points out, sex predilection alone rules out the possibility that the disease originates in the nose, since there is no nasal disease which is five times more common in females. According to Garfin,[21] Meller and Schaeffer believe that the anatomic difference of the nasal bones causes the lumen of the lacrimal canal to be narrower in women than in men. Traquair has noticed an hereditary factor in 11 percent of the latter part of his series.

It is of unusual interest here that congenital occlusion of the lacrimal ducts occurs about equally in the two sexes. It is also well known that congenital occlusion of the lower end of the canal is cured in the great majority of cases during the first year of life by massage only, and if this conservative treatment fails, one probing at the age of 6 to 12 months almost always gives complete relief without a tendency to become occluded again.

BACTERIOLOGIC PICTURE

Traquair did a bacteriologic examination of the conjunctival sac in 251 cases of oc-

clusion of the lacrimal sac of duct in which Toti's operation was subsequently performed, and repeated the examination in 95 of the cases after the operation. He did not state how long after the operation the second examination was made, nor whether he made more than one postoperative examination. Two hundred and twenty-five eyes examined before cataract extraction were used as controls. No growth was found in 12 percent of the cases of lacrimal obstruction, nor in 16 percent of the controls. Pneumococci or streptococci were found in 32 percent of the cases of lacrimal obstruction, and in 6 percent of the controls. Staphylococci were found in approximately the same percentage of cases in each group. The effect of dacryocystorhinostomy was to reduce the streptococci from 32 to 11 percent; whereas, the control group showed 6 percent. Several cases of cataract extraction were performed by Traquair after the Toti operation, and Arruga[22] reported more than 30 cataract extractions after the Dupuy-Dutemps dacryocystorhinostomy, without any infectious complication. According to Garfin,[21] Rollet and Bussey's series of obstruction of the lacrimal sac showed pneumococci in 60 percent, streptococci in 10 percent and no bacteria in 26 percent. They found mucoceles to be almost sterile.

INDICATIONS FOR DACRYOCYSTORHINOSTOMY

The operation is indicated in stricture of the nasolacrimal duct or any portion of the lacrimal sac, or in cases of absence of the lacrimal sac, provided the lower punctum and lower canaliculus are normal.

Dilation of the lacrimal obstruction should be attempted in every patient, regardless of how long-standing the condition. One patient suffering from an acquired unilateral obstruction of 20 years' duration was completely relieved of tearing and mucopurulent discharge by a single probing. The passage of a probe should be attempted in order to learn the level of the stricture. However, if

passing a No. 2 or 3 Bowman probe all the way into the nose does not relieve the obstruction after 2 or 3 weekly probings, it is useless to continue. In fact, repeated probings that progressively dilate the lower punctum are contraindicated, since they will cause tearing after a subsequent dacryocystorhinostomy. The lower canaliculus should never be slit, for the same reason. If an external fistula is present, it is disregarded in performing the operation, and it will close spontaneously, within a few days after reestablishing lacrimal drainage into the nose.

CONTRAINDICATIONS FOR DACRYOCYSTORHINOSTOMY

If either the lower punctum or lower canaliculus is not normal, watering will continue after the operation but the patient will be relieved of mucopurulent discharge. A normal upper punctum and upper canaliculus will usually not keep an eye free of tearing if the lower punctum and lower canaliculus are not functioning. The operation should not be done in tuberculous or malignant involvement of the sac, and should be postponed for at least a month after any acute inflammation of the sac or nose has subsided. Any obstruction in the nose should be remedied, and the patient allowed to recover from the procedure, before dacryocystorhinostomy. There is almost no age limit for the operation, if the patient is otherwise in good health. The youngest of my series was aged 4 years and the oldest, 73, and other surgeons have reported successfully performing the operation on even younger and older patients. The younger the patient the softer is the bone, and it is proportionately easier to make the bone window. The dimensions of the anatomic parts involved in the young are surprisingly close to the dimensions found in the adult.

Stallard[23] in 1940 reported on original operation that was successful in relieving epiphora in a patient who had both canaliculi cut in an accident. The upper end of the

sac was dissected from its bed, and transplanted through a stab wound into the lower cul-de-sac. After the upper end of the sac was sutured to the conjunctiva, anteriorly and posteriorly in the depth of the lower cul-de-sac, the dome of the sac was excised. This procedure might be found more effective than trying to reconstruct canaliculi and puncta.

TECHNIQUE OF THE OPERATION

ANESTHESIA

The usual preoperative sedatives should be given. The operation can be done under local or general anesthesia, depending entirely on the excitability of the patient. If general anesthesia is thought advisable, sodium pentothal intravenously has been found to be the most satisfactory, since it reduces to a minimum the necessity of the anesthetist working near the operative field. If ether anesthesia is preferred, after induction with gas or the ether cone, it should be vaporized by the ether machine through the side-lip mouth airway into the nasopharynx, thus eliminating the necessity of the ether cone.

If local anesthesia is desired, a long pledget of cotton saturated with one-percent pontocaine or nupercaine, or 4- to 10-percent cocaine, is placed high in the nasal fossa on the side to be operated. The face and operative area is cleansed in the manner that is usual for any ocular operation. It is best not to instill topical anesthesia into the eye, since the patient's normal blink reflex is desired to make him protect his cornea by keeping his lids shut.

Two-percent procaine hydrochloride, containing five drops of 1:1,000 epinephrine hydrochloride to the ounce, is injected into three areas, using a long, fine (27 gauge) needle. A small amount, about 0.5 cm., is injected along the site of the incision just beneath the skin; 2 cc. is injected just below the supraorbital notch, extending downward along the periosteum, infiltrating the region of the dome of the sac. This anesthetizes the supraorbital nerves supplying the upper

end of the sac. Another 2 cc. is injected in and over the infraorbital foramen, the last portion of which is directed upward and inward to infiltrate the region of the lower end of the sac. This anesthetizes the infraorbital nerve supplying the lower end of the sac. The surgeon stands at the side of the patient and the assistant stands at the top of the patient's head.

THE SKIN INCISION

The incision is made straight, as suggested by Mosher and reëmphasized by Hogan, because scar-tissue contraction accentuates the scar if the incision is curved. The incision is begun about 8 mm. nasally and level with, or 1 mm. below, the inner canthus (fig.1). If slight traction with the thumb is made on the soft tissue on the bridge of the nose to the side opposite the operation as the incision is being made, the angular vein and artery will not be cut as often. The initial incision is extended down through the periosteum in its entire length of about 2 cm. The incision extends downward and slightly outward, and should be made with one continuous stroke in order to obtain a straight skin incision. If a large vessel is cut, time will be saved if it is tied with catgut.

The Stevenson lacrimal sac retractor is inserted into the incision and spread tightly. This exposes the depth of the incision, and the pressure helps to control the bleeding. The internal palpebral ligament is not cut, unless the preoperative probing has shown the stricture to be high in the sac, that is, on the level with or just below the inner end of the lower canaliculus. The assistant's main duty is to keep the operative field free of blood by using the suction tip constantly. It is unnecessary to stop the oozing type of bleeding until the bony window has been completed. The best source of illumination is the large overhead portable spotlight with the light passing just above the surgeon's head.

A periosteal, or nasal mucous membrane, elevator is used to push the periosteum nasally and laterally. The first and only

real landmark is the anterior lacrimal crest which is uncovered as the periosteum is pushed laterally. The entire length of the crest is uncovered from the internal palpebral ligament above, downward to and including the lower extremity, where the crest turns laterally to form the anterior rim of the upper end of the nasolacrimal canal. The

The gouge is gently driven with the mallet so that a thin slice of bone is removed along the entire length of the anterior lacrimal crest up to the internal palpebral ligament. If the head block that is used in mastoid surgery has been previously placed under the patient's head, there will be less jarring produced by the mallet. Successive slices of
Figs. 1 to 5 (Hallum). (Fig. 1) The incision. (Fig. 2) Beginning the bony window, with the gouge astride the lower end of the anterior lacrimal crest. The assistant stands at the top of the patient's head, keeps the sac pushed laterally and uses the suction tip constantly. (Fig. 3) Several long, thin slices of bone have been removed and a small area of nasal mucous membrane has been exposed. (Fig. 4) Anterior and posterior flaps are made by making capital I incisions in the medial wall of the lacrimal sac and in the nasal membrane. (Fig. 5) The posterior flaps have been united. The sutures have been placed in the anterior flaps, and each suture includes some tissue on the anterior rim of the bony window, so that when the sutures are tied the flaps will be united and lifted out of the new passageway.

sac is easily separated from the floor of the fossa and pushed laterally to expose the posterior lacrimal crest.

PERFORATION OF THE BONE

For this procedure a mallet and bone gouge about 1 cm. wide (No. 8 or 10) is preferred. The gouge is set astride the lower end of the lacrimal crest where it turns laterally to form the anterior rim of the nasolacrimal canal (fig. 2). The assistant keeps the sac pushed laterally, using a nasal mucous membrane elevator as a retractor.

bone are removed in the same manner until in the bottom of the grove a small area of nasal mucosa is uncovered (fig. 3). This small bony opening is enlarged with a small bone curette, until the opening in the bone is large enough to admit the Kerrison forceps. Care must be taken not to perforate the nasal mucosa.

The opening in the bone is enlarged with the Kerrison forceps and sharp-pointed ronguer forceps. The window should be made low enough so that it extends down to the level of the upper end of the nasolacrimal

Fig. 6 (Hallum). The correct location of the bony window is outlined on the skull, astride the anterior lacrimal crest. The lower margin of the opening extends down to the upper end of the nasolacrimal canal.

vens' scissors are often useful in completing the upper and lower ends of the incision. A probe should be passed through the lower canaliculus into the sac and out through the incision in the sac wall to insure the fact that all layers of the sac wall are incised and that there are no other obstructions. The upper and lower ends of the incision are extended anteriorly and posteriorly from 1 to 3 mm., changing the vertical incision to the shape of a capital I, and forming a posterior and anterior flap.

Before making a similar incision in the nasal mucosa, all bleeding should be stopped. The retractor should be removed, the wound packed with cotton saturated with adrenalin, and pressure applied for 2 or 3 minutes.

After replacing the retractor, the site of the vertical incision in the nasal mucosa is then determined by grasping the posterior flap of the sac with forceps and drawing it medially toward the nasal mucosa. At the place where the flap touches the nasal mucosa, an incision is made parallel to the incision in the sac, extending to the upper and lower rims of the bony opening. The upper and lower ends of the incision are extended anteriorly and posteriorly, as was done to the incision in the sac, forming anterior and posterior flaps of nasal mucosa. It is unnecessary to make posterior flaps when the sac lies in contact with the nasal mucosa after the bone has been removed; indeed, in such cases it is occasionally unnecessary to make anterior flaps.

If the anterior end of the middle turbinate should be found to be more or less completely blocking the opening in the nasal mucosa, the visible portion of the turbinate should be excised through the incision with scissors or biting forceps. The small amount of bleeding that might follow can be controlled easily

canal (fig. 4). The bone forming the floor of the lacrimal fossa and enough of the bone medial to the anterior lacrimal crest is removed to make the horizontal diameter of the opening at least 10 mm. The opening is extended upward so that the vertical diameter is at least 12 mm. The opening in the bone must be made as low and as far forward as possible in order to avoid the ethmoid cells, and to place the opening anterior to the tip of the middle turbinate (fig. 5).

THE MUCOSAL INCISION

The nasal wall of the lacrimal sac is incised vertically from a point opposite the upper margin of the bony window to a point opposite the lower margin of the bony window (fig. 6). A No. 15 Bard-Parker knife blade serves best for this incision, but Ste-

by pressure applied to gauze inserted through the nares. The presence of polypi found in the same site should be treated in the same manner.

SUTURE OF THE MUCOUS MEMBRANES

The depth of the operative wound at this stage is usually as great as the length of the vertical skin incision and it is necessary to use extremely short needles in placing the sutures to unite the respective flaps, especially the posterior flaps. Probably the best needle available for this purpose is supplied by Davis & Geck, Inc., New York, and can be ordered by asking for Product C 269. Each of the ampules contains a 3-0 chromic catgut suture armed at each end with a one-half circle one-fourth inch atraumatic needle; each such double-armed suture is enough for one dacryocystorhinostomy.

The posterior flaps are first united by placing a suture at the upper and lower ends of the flaps; occasionally, only one suture is necessary (fig. 7). The anterior flaps are united in a similar manner by placing a suture at the upper and lower ends, except that each suture includes an additional bite of tissue close to the periosteum on the rim of the bony window superiorly and inferiorly, respectively. When these sutures are tied, after loosening or removing the retractor, they not only approximate the margins of the anterior flaps but lift them forward out of the bony window. Thus a new, open, epithelial-lined passageway extends from the lacrimal sac into the nose. The new passageway stays open because the epithelial lining prevents the formation of granulation tissue and adhesions.

CLOSURE OF THE SKIN AND DRESSING

Two or three subcutaneous sutures should be taken with the plain catgut, so that the skin can be approximated without traction on the skin sutures. The skin inci-

Fig. 7 (Hallum). The bony window, when correctly placed, opens into the nose just anterior to the tip of the middle turbinate.

sion can be closed equally well with interrupted or running silk, or with a subcuticular suture. Occasionally no skin suture is necessary. Five-percent sulfathiazole ophthalmic ointment is instilled inside the lids and along the skin incision. A thin layer of petrolatum is spread on the undersurface of the gauze eye patch which is applied over the closed lids. Additional gauze fluffs are added and moderate pressure is applied by placing several strips of one-inch wide adhesive diagonally from the forehead to the cheek.

POSTOPERATIVE CARE

At the completion of the operation the patient should lie face down for a few hours so that any bleeding into the nose will not be swallowed. It has not been necessary in a single instance to pack the nose to control postoperative hemorrhage. Usually only a few drops of blood trickle out the nose during the immediate postoperative period.

Bathroom privileges and regular diet are allowed 12 hours later, and the patient may leave the hospital at the end of 48 hours, after the dressing and skin sutures have been removed and a regular gauze eye patch applied.
Fig. 8 (Hallum). (Arruga[22]). Canaliculirhinostomy. A vertical incision is made over the prominence of the end of the probe as it is held in the lower canaliculus. The margins of this incision serve as anterior and posterior flaps.

Physiologic solution of sodium chloride may or may not be irrigated through the lower canaliculus into the nose, using a syringe and needle, but apparently this is unnecessary. However, it makes both the patient and the surgeon happier to know that the new passageway into the nose is open. If fluid fails to pass from the lower canaliculus into the nose, the nose on the side of operation should be examined for obstruction produced by edema in the region of the bony window.

Edema of the nasal mucosa usually can be relieved easily by instilling some vasoconstrictor, either by drops or on a cotton pledget. Then if the fluid fails to pass from the lower canaliculus into the nose, a probe must be passed into the nose through the lower canaliculus and bony window, to break adhesions by gentle movements of the probe.

The patient is dismissed at this dressing if the skin incision is united and free from infection, and he is asked to remove the eye patch 48 hours later. He is warned against opening the incision by pulling on the skin in the region of the operation for a few days.

RECURRENCE

The patient is advised to return at the end of a week if epiphora persists, or at any subsequent time if epiphora returns, at which time the nasal mucosa must be shrunk with a vasoconstrictor and a probe passed to break adhesions. No cases of late obstruction of the new opening have been encountered, that is, several weeks or months later, but if such a complication should occur the procedure as described by Arruga[22] should be tried. He dilates the lower canaliculus until it admits a Weber knife, with which the membrane covering the bony window is incised across its complete diameter.

OPERATION IN CASES OF ABSENCE OF THE LACRIMAL SAC

When the lacrimal sac has been previously removed, or is completely occluded, reestablishment of lacrimal drainage into the nose can be obtained by slight variations of the above technique, if the lower punctum is normal and if the lower canaliculus is in good condition along its entire length. Arruga[22] first described this latter procedure and thinks that such an operation should be successful in two thirds to three fourths of the cases. Gifford reports two successful results in three cases, and Hogan one cure in three cases. Two of my series have been successful.

After the customary incision and exposure, the opening in the bone is made slightly larger so that longer flaps of nasal mucosa can be obtained. The medial end of the inferior canaliculus is identified by introducing a probe and maintaining pressure. A vertical incision is made in the tissue covering the prominence of the end of the probe, until the probe passes freely through the incision (fig. 8). The incision is deepened and lengthened until the anterior and posterior lips of the wound actually serve as fair anterior and posterior flaps. The remainder of the operation is the same as in the classic dacryocystorhinostomy.

In my two cases the only variation from Arruga's technique was threading a small silk suture through the lower canaliculus into the nose between the posterior and anterior flaps. This suture was placed after uniting the posterior flaps, but before uniting the anterior flaps. The end of the suture was brought out the nares and tied on the cheek to the other end of the suture. This suture was left in place for three weeks and the patient moved the entire circumference of the suture once daily by pulling the suture out of the nose for one-half inch or so. It was thought that this in-dwelling suture would prevent adhesions and encourage epithelization of the channel along the suture at the newly opened medial end of the lower canaliculus.

REPORT OF SIXTY CASES

Eight years ago it was decided to substitute dacryocystorhinostomy for extirpation of the lacrimal sac. Between January, 1940, and February, 1948, 60 dacryocystorhinostomies were performed, using the technique of Dupuy-Dutemps.

A follow-up has been obtained on 55 of these cases. Only one patient, the 21st operation in the series, reports no relief of pus or tearing, and refuses to return for examination. Her operation was uneventful four years ago at the age of 66 years, and my records show that at the first dressing normal saline solution was irrigated freely into the nose through the lower canaliculus. One other patient, the 13th operation in the series, who for four months had complained of epiphora only was not relieved. It was thought the stricture was in the naso-lacrimal duct, but it must have been a mistaken diagnosis, because at the recent follow-up examination six years after the operation, it was found that both upper and lower canaliculi were occluded to within 2 mm. of the puncti.

Six other patients were relieved of pus but were not completely relieved of tearing; in four of these patients the lower punctum was found at the follow-up examination to
Fig. 9 (Hallum). Punctorrhaphy. (a) Normal punctum. (Added by artist): (b) Dilated punctum. (c) A cataract knife is used to denude the inner rim of the punctum, except its nasal portion. (d) Silk sutures have been placed across the margin of the lid, just deep enough to include the lips of the punctum. (e) After the sutures have been tied, the punctum is reduced to its normal size.

be dilated beyond normal size, one had had his lower canaliculus slit, and one had occlusion of the lower punctum. Punctorrhaphy (fig. 9) has been performed on two of the patients who had dilated lower puncta, and each has been completely relieved of tearing. In each of these cases the lower punctum was anesthetized by injecting a few minims of 1-percent procaine hydrochloride just anterior, and posterior, to the punctum. The tip of a cataract knife was used to produce denudation of the inner rim of the dilated punctum, except in the extreme nasal portion. A fine silk suture was placed across the lateral half of the punctum, from the anterior to the posterior lip, and left snugly tied for four days. In each of the two cases the decrease in tearing was immediate, that is, at the end of the operation.

Twelve of the patients were Negroes, seven of the patients had bilateral operations. Four of the patients who had bilateral operations were women, and three were men; all three of the men had bilateral con-

genital stenosis. There was only one patient who had unilateral congenital stenosis. The longest period of obstruction was 28 years —one of the men who had bilateral congenital stenosis. Thirty-five of the operations were done on the left side, and 25 on the right side.

Ten of the operations were done by the senior ophthalmic resident, under my direction, and all 10 operations were successful. Thirty-seven of the operations were performed under sodium pentothal intravenously and 23 under local anesthesia. Trauma was thought to be responsible for the obstruction in 10 of the patients; in one patient the obstruction developed after an antrum operation and the other nine followed blows on the nose, mostly in automobile accidents.

Two of the patients had external fistulas at the time of the operation, but they closed spontaneously after drainage into the nose was reëstablished. An abrasion of the cornea was produced in two patients; the abrasion healed in the normal time and without complications.

CONCLUSIONS

Dacryocystorhinostomy has given many

surgeons the highest percentage of successful results when done by the technique popularly known as that of Dupuy-Dutemps. Extirpation of the lacrimal sac leaves tearing in a high percentage of the cases, but dacryocystorhinostomy by the technique of Dupuy-Dutemps should relieve both tearing and mucopurulent discharge in at least 95 percent of the cases of obstruction of the lacrimal duct and sac, if the lower punctum and lower canaliculus are normal. Even if the lacrimal sac is absent or completely occluded, tearing should be relieved by this operation in the majority of the cases. The postoperative treatment is usually limited to the care of the skin incision.

Excessive dilation of the lower punctum should be avoided, as it will result in tearing in an otherwise successful dacryocystorhinostomy. For this reason, the lower canaliculis should never be slit, and one should never pass a probe larger than a Bowman No. 2 or 3 lacrimal probe. A dilated punctum when partially closed by punctorrhaphy can be expected to relieve the accompanying tearing.

OCULAR ONCHOCERCIASIS*

M. Puig Solanes, M.D., Bertha Riveroll Noble, M.D., and A. Fonte, M.D.
Mexico City, Mexico

Translated by George P. Guibor, M.D.
Chicago, Illinois

More than 30 years ago, ocular onchocerciasis was reported by Rodolfo Robles[1] and its clinical characteristics were described by Pacheco Luna.[2] Clinical material was accumulated by Fonte from data obtained at Huixtla, Chis., Mexico, in 1943; from records compiled by Puig Solanes, Fonte, and Quiroz[3] in the same locality in 1945; and from studies of Bertha Riveroll Noble[4] in the endemic zones of Guatemala.

Nearly all of the 1,334 cases examined by these investigators presented the characteristic nodules of onchocerciasis and possessed positive cutaneous biopsies. In a few cases, the existence of nodules could not be demonstrated and the cutaneous biopsies were not always positive. These patients, however, did present ocular lesions in the form of superficial punctate keratitis and iridocyclitis.

Only three complete globes and a number of fragments of corneal and conjunctival tissue were obtained for study by Noble[4] and Vargas de la Cruz.[5] Enucleation is unnecessary in most cases of ocular onchocerciasis, but delay in treatment has caused almost complete destruction of the globe, in some instances, before enucleation could be performed.

Strong[6] reported the incidence of ocular involvement in 5 percent of the cases in the Guatemalan zone, while Calderón[7] found ocular symptoms in 100 percent of the cases in the same zone. The disparity in these percentages results from the variation in susceptibility among individuals and the additional fact that, in those districts in which there are facilities for periodic examination and treatment, fewer eye infections occur. In addition, examinations performed in many rural districts without the aid of the biomicroscope do not reveal the existence of early ocular lesions.

In Africa, Hissette[8] found ocular lesions of onchocerciasis in from 43 to 51 percent of those infected, in the villages of the Belgian Congo, and we found 66.3 percent among the 1,334 patients examined in other zones.

Statistical studies made by us disclose that ocular involvement in onchocerciasis is not varied or influenced by the age of the patient or by the duration of the disease. A significant difference in incidence of infection of the eyes was noted in relation to the number of the nodules present regardless of size, 77.2 percent in those with more than five nodules and 60 percent in those with less than five nodules.

Strong[9] reported that, on his African expedition, ocular complications were particularly frequent in patients with small but numerous nodules (25 to 100). In the study of the susceptibility of various races to the disease, it was indicated that the Caucasian race is less susceptible than the races native to the Americas and to Africa and that those of mixed genesis show a definite predisposition to infection. There were more men than women infected.

CLINICAL ASPECTS OF ONCHOCERCIASIS

ACUTE FORM

In the acute form of onchocerciasis, the skin and the eyes are severely affected. The hard, red swellings in the skin of the cheeks, eyelids, and about the ears (figs. 1 and 2) were diagnosed by Robles[1] "as erysipelas of the skin."

Ocular manifestations in the acute form are photophobia, blepharospasm, lacrima-

Fig. 1 (Solanes, Noble, and Fonte). Facial appearance in onchocerciasis.

tion, and injection of the anterior segment with edema between the superficial and deep tissues so great that on moving the globe, there is the appearance of a hyperplasia. The dermal irritation persists after the ocular symptoms have subsided but both reappear in the chronic form unless the skin is cleared of infestation.

THE CHRONIC FORM

The chronic form, the "true conjunctivitis of Calderon,"[7] existed in 22 percent of the cases of Puig Solanes, Fonte, and Quiroz. This form is characterized by vascularization and excessive pigmentation, resulting from small irregular granules in the epithelium. In the conjunctiva (fig. 3) are follicles resembling phlyctenules.

Corneal manifestations. Superficial punctate keratitis, the characteristic corneal lesion in onchocerciasis, appeared alone in 45 per-

cent of the cases of Puig Solanes, Fonte, and Quiroz[3] and was associated with iridocylitis in 20 percent of the cases.

Pacheco Luna[2] described these opacities as being a fraction of a millimeter in size and numbering from 1 to 12 in the same cornea, scattered, generally, but sometimes coalesced near the limbus. The biomicroscope shows them to be of powdery consistency in the vicinity of Bowman's membrane.

Interstitial keratitis, reported by Calderón,[7] is now believed to be only aberrant lesions of the superficial type. Vascular keratitis was noted by Hissette[8] as vascularization of the corneal limbus enmeshed in a weblike structure resembling a true pannus.

Chronic manifestations of the iris. Iritis, in association with lesions of the cornea, was demonstrated in 29 percent of the cases of Puig Solanes, Fonte, and Quiroz.[3] Puig Solanes[10] described fibrinous iritis with

Fig. 2 (Solanes, Noble, and Fonte). Cutaneous lesions of onchocerciasis.

and without displacement of the pupil. Calderón[7] spoke of acute and chronic forms, while Hissette[8] called it "diffuse atrophy of the iris."

Excessive pigmentation is present, in this manifestation, with microscopic obliteration of the folds of the iris. Exudation may occur near the pupil with synechias in the lower portion of the membrane (fig. 4). Gonioscopic studies of Puig Solanes[11] of 30 eyes of patients with onchocerciasis disclosed that the root of the iris is affected.

Choroidal manifestations. Choroidal involvement is noted most frequently in Africa. Hissette[8] described it as a diffuse

Fig. 4 (Solanes, Noble, and Fonte). The effect of iritis in onchocerciasis.

Fig. 3 (Solanes, Noble, and Fonte). Conjunctival alterations in onchocerciasis.

pigmented chorioretinitis with patches of atrophy.

SUBJECTIVE SYMPTOMS

Subnormal vision. Visual acuity is decreased in ocular onchocerciasis principally from opacities in the cornea. There is, in the acute type, recovery upon removal of the nodules.

Other subjective symptoms. These symptoms may exist with or without the presence of objective lesions. The principal discomforts noted are the so-called conjunctival triad—fever, pain, and the sensation of a foreign body in the eye.

This triad is frequently linked with dancing lights, photophobia, entoptic vision of

active microfilaria, poor visual acuity, and lacrimation.

DIAGNOSIS

Microscopic demonstration of the existence of microfilaria in the eye (fig. 5), positive cutaneous or conjunctival biopsies, and verification of the characteristic nodules constitute the general clinical diagnosis of onchocerciasis.

Parasites in the eye. Clark and Noble saw filariform bodies in the vitreous cham-
Fig. 5 (Solanes, Noble, and Fonte). Biomicroscopic representation of microfilaria in the anterior chamber.

ber but did not verify the type of filaria present. In 1945, Torres Estrada,[12] with the aid of intensive illumination and a lens of 20 to 25 diopters, demonstrated microfilaria as blackish filaments in the lower portion of the vitreous chamber.

Biomicroscopy of the eye. Torrella[13] first saw microfilaria in the anterior chamber of the eye by means of the biomicroscope in

sue. The number of microfilaria varies from day to day in the same individual. We found 16.3 per cent of our group with positive cutaneous biopsies and only 5 percent with positive conjunctival biopsies.

EXAMINATION OF NODULES IN THE SKIN

The nodules are of the greatest value in the diagnosis of onchocerciasis. They are
Fig. 6 (Solanes, Noble, and Fonte). A magnification of the adult parasites occupying the center of the mass of atrophied connective tissue in which the young are born.

1930. The parasites appeared to be refractive, thin, and to move about incessantly. The number varied from one to dozens and from day to day in the same patient. The parasites appeared to be phototropismic.

Biomicroscopy of the skin and the conjunctiva. Thin slices of the skin or of the conjunctival tissue are prepared for use with the biomicroscope in the usual manner with water or with whey. From 1 to 20 active microfilaria may be seen to 1 mm. of tis-

from 0.75 of a millimeter to 3 or 4 cm. in size. They are hard, not painful, and are adherent to the skin. They are found most frequently about the head, on the American continent, in numbers not over 7 or 8. In Africa, the trunk and the limbs may show as many as 25 to 100 nodules in a single patient. The nodules may exist also in the outer canal of the ear, in the lining of the cheek, and over the aponeurosis of a muscle (Nettel[14]). The nodules are filled with a

turbid liquid containing active microfilaria which swim about a core of adult parasites enmeshed in connective tissue in a state of atrophy (fig. 6).

HISTOLOGIC PATHOLOGY

Octerena,[15] Hissette,[8] Strong,[6] and the authors[3] studied the histologic pathology of ocular onchocerciasis. Their conclusions were similar in most instances. The following are our conclusions:

1. The corneal lesions are superficial and exhibit much vascularization and pigmentation.

2. The activity of the microfilaria observed in the histologic preparations is comparatively small in relation to the extent and the number of the corneal lesions encountered.

4. Atrophy of the stroma of the iris occurs frequently.

5. The attack on the posterior pigmented portion of the epithelium and the dilator muscle is sufficient to explain the paresis of the pupil.

6. The ophthalmoscopic appearance of the choroidal atrophy and of dispersion of the pigment in the choroid is similar to the atrophy seen in the iris.

7. The retinal alterations seem to be secondary to the choroidal alterations and to exist principally in the outer layers of the retina.

PATHOGENESIS

The pathogenesis of ocular onchocerciasis can be accounted for by the action of toxins generated by the filaria in the nodules (Robles[1] and Pacheco Luna[2]). It is possible that the periodic reproduction of the females may bear some relationship to the toxins produced (Calderón[7]).

The traumatic action of the microfilaria in situ in the ocular tissues may result in much disturbance, especially if the nodule is near the eye and contains female adults which produce larvae every two months (Nettel[14]). We are of the impression that there are fac-

tors other than these which are still undiscovered.

The morbidity in ocular onchocerciasis may accrue also from the products of the metabolism of the adult parasite or of its larvae (Martinez Baez[16]). However, Hissette[8] was the first to discover the tenuous refractive filaments in the corneal parenchyma of patients. These are the dead microfilaria. Torres Estrada[12] considered that the lesions of keratitis centered in the vicinity of these dead bodies.

There is also much controversy over the manner in which the parasite enters the globe. The logical manner is from the external toward the deeper portions of the eye but Hoffman and Vargas[17] and Nettel[14] hold the theory that they proceed from some hidden nodule to the inner portions of the eye. Nettel[14] presented cases of patients with microfilaria present in the ocular chambers but none in the eyelids or in the subconjunctival tissues.

PROGNOSIS

In general, the prognosis is not good. Microfilaria persist in the eyes months after the removal of the nodules from the skin. Considering the severity of many individual lesions, however, the visual acuity is good, especially in some of those cases in which there are many corneal opacities. In 45 of 61 cases there was visual acuity of 10/10 and in only 3, below 7/10.

Iritis in onchocerciasis, however, alters the vision considerably. The following percentages exclude incipient attacks of iritis, glaucoma, bulbar atrophy, and so forth, or of their sequelae. In iritis, there was visual acuity 10/10 in only two eyes of 22 examined, 1/10 in one of the eyes, 9 above 1/20 and 9 below 1/20. One eye was completely blind.

TREATMENT

The use of plasmoquina discussed by Torrella[13] has not proved permanently effective in the destruction of microfilaria.

Pacheco Luna has found surgical intervention disastrous in the treatment of affections of the iris.

The modern treatment of Bayer 205 (no reference given) would aid many if it were to . prove generally as effective as it has proved in Africa.

We are of the opinion, however, after 10 years of systematic effort on the part of the sanitary ministers of Mexico and of Guatemala, that it has been proved that periodic examinations and removal of the nodules of onchocerciasis lessens the number of acute attacks and decreases the number of microfilaria in circulation. This reduces the prob-. ability of ocular infection.

SUMMARY

A study of over 1,000 cases of onchocer-ciasis revealed an ocular infection in 60 to 77.2 percent of the cases. Caucasians were less susceptible, whereas those of mixed genesis were most susceptible.

Acute and chronic forms existed. In the former, the skin and the eyelids contained many papules.

In the chronic form, all tissues of the eye were infected, the cornea in 45 percent, iridocyclitis in 29 percent.

The diagnosis is made by: (1) The history of residency in the affected areas of Mexico, Guatemala, and Africa; (2) clinical signs and symptoms of nodules; (3) finding the microfilaria in the eye by slitlamp, and in the skin nodules by means of the microscope. The latter method is considered the most reliable.

OCULAR LYMPHOMAS*

PARKER HEATH, M.D.
Boston, Massachusetts

Ocular malignant lymphomas are uncommon. Hyperplasia of lymph and reticular tissue, however, is a common reaction to infection. Lymphoid elements are widely distributed under and in the conjunctiva of lids and globe, in the lacrimal gland, and in the lymph drainage system. The wide distribution and ready mobilization cause the borderlines of hyperplasia and malignant new growths to be far from sharply drawn. The lymph cells, however, even though they may undergo marked changes when they become neoplastic, still will tend to reproduce the cell of origin. This permits a classification based upon the principal cell types.

The purposes of this study of a significant series of ocular lymphomas are: to report the incidence, to classify the cases studied clinically and according to the principal cell types, and to report separately on both the incidence and the results of treatment of conjunctival lymphomas.

The material for this series was obtained from Massachusetts General Hospital, Collis P. Huntington Memorial Hospital, and the Massachusetts Eye and Ear Infirmary. Sixteen hundred records of patients with lymphomas of all varieties were consulted from the three institutions.

Ophthalmic literature, in contrast to that of general medicine, has scanty references to lymphomatous disease. Detailed reviews of the literature have been made by Shannon and McAndrews,[1] Leinfelder and O'Brien,[2] Ennema,[3] and McGavic.[4] Case reports on reticulum-cell sarcoma of the conjunctiva have been made by Siotto,[5] Black,[6] and Rados.[7] Verhoeff and Derby[8] report a case of plasmoma of the lacrimal sac and cite nine other cases reported. Because of the rarity of ocular lymphoma, most reports are made from small series. Ophthalmologists in general see but few of these patients. Laboratory reports are often confusing. The variety of early clinical signs and the irregular periods of remission of the disease combine to obscure further both reports and satisfactory classifications. One would expect this in a disease of unknown etiology and such wide variance in clinical manifestation. The reports in medical literature reflect this by showing variegated classifications, terminology, and conclusions. The matter of etiologic agent is not considered in this paper.

Clinically, the lymphomatous lesions are usually painless, moderately firm and vascular, and slow in growth. When presenting under a mucous membrane they appear grayish pink and yellowish pink to red and show coarse vessels superficially. Early stages may somewhat resemble a firmer kind of lipoma. They range in size from small, firm, discrete nodules in lid, globe, or orbit, to diffuse masses of tissue encircling the globe or involving the lids and found within both orbits. Biopsy removal and microscopic examination is of greatest value in diagnosis.

A clinical classification can be made based upon the appearance and the course of the growth as follows:

1. Benign hyperplastic node, located usually episcleral or subjunctival behind the lower or upper lid. It is a smooth-surfaced, fleshy nodule, yellowish pink in color without signs of inflammation. These often remain the same size for years, are sometimes congenital, but may develop malignant qualities, especially in the first and after the fifth decade of life.

2. Locally diffuse: (a) conjunctival or subconjunctival, grayish in color, somewhat

soft, gelatinous clusters of lymphoid tissue, with limited growth; very sensitive to X rays and not likely to recur; (b) this group is benign, at first lymph-cellular, later a fibrous, scirrhous, lymphoid hyperplasia involving lacrimal gland and lids, and the or-

may be found in skin, episclera, subconjunctiva, and orbit. As a rule these nodules become invasive relatively slowly. When the limbus is involved, there may develop a superficial pannus and red fleshy corneal overgrowth with rare superficial hemor-

bit in a self-limited extension; the "pure" form of Mikulicz's disease (Heath[9]).

3. *Associated ocular lymphoma*, eye involvement as part of general disease, leukemia or Hodgkin's and of the hematopoietic system including spleen, bone marrow, and lymph nodes, and liver. Small lymphomas

rhages. The insertions of the recti muscles or the plica and caruncle may be the sites of nodules. These nodules are composed of mature lymphocytes and of lymphoblasts showing a moderate reticulum and a stroma carrying blood vessels and capillaries.

4. *Invasively diffuse:* first seen as an ex-

panding, grayish pink, firm to hard, bulbar, subconjunctival, lid or orbit new growths, sarcomatous, and invasive by lymph channels; may be derived from group (1) or (2a) if the local process shows mature cells which have become more primitive and invasive. The conjunctival and subconjunctival red encircling swelling is firmly attached to the globe and has somewhat the

than chalazion. A biopsy, which should include part of the nodule, may show a reticulum-cell lymphoma.

This report uses the classification developed by Sparling, Adams, and Parker (Table 1).[10] It survives the test of usefulness in predicting the clinical course of the disease. The cells of the lymph structure

tached to the globe and has somewhat the appearance of a brawny scleritis and some superficial capillary hemorrhages may be noted. When it occurs in the lid, an extensive firm edematous swelling is noted to be associated with a deep smaller nodule which is both opaque and shows frayed edges on transillumination. The process resembles at first inspection an acute chalazion with edema, but has less hyperemia; the vessels are fewer and coarser and small hemorrhages may be noted. The swollen lid is firmer and gives less pain to the patient on palpation

used in the classification are: lymphoblasts, mature lymphocytes, the reticulum cell, and the plasma cell.

When local lymph tissue extends and invades, it is called sarcomatous, and when found in the blood it is called lymphatic leukemia; the presence of Reed-Sternberg cells makes the diagnosis Hodgkin's disease. Table 2 gives cytologic detail. Four cell types are illustrated by photomicrographs selected from this series, a fifth to depict Hodgkin's disease.

Sixty-seven cases of ocular lymphoma

Fig. 4 (Heath). Plasmoma ($\times 1,200$). Plasmocytoma (2 to 12 micra). Polygonal or triangular outline. Nucleus round, eccentric. Chromatin masses in the periphery. Basophilic cytoplasm. No increase of reticulum.

Fig. 5 (Heath). Hodgkin's disease. Always shows Reed-Sternberg cells (10 to 40 micra). Pleomorphic nucleus, sometimes lobulated and multinuclear. Nucleoli common, large clumps of chromatin. The Reed-Sternberg cells are the large multinuclear cells.

TABLE 2

CYTOLOGIC DIFFERENTIATION

	Size	Nucleus	Cytoplasm	Reticulum	Mitosis	Necrosis	Local	Invasive
Lympho-blast	9 to 20 micra	Larger than mature cell. Border well defined; finely divided chromatin dispersed in nucleus. Single	Narrow; border may stain basically	Not increased	Rare	Rare	Lymphoblastoma	Lymphosarcoma of lymphoblastic type
Lympho-cyte	7 to 10 micra	Dense; massed chromatin	Slight; basic	Not increased	Rare	Rare	Lymphocytoma	If in blood, lymphatic leukemia. Lymphosarcoma of lymphocytic type
Giant follicle Lymphoma	Many separate or fused large follicles with active germ centers. Usually limited to lymph nodes and spleen	Germ centers contain young lymphocytes or reticulum cells					Border zone of mature lymphocytes	Half develop Hodgkin's or sarcoma
Reticulum cell	10 to 20 micra	Ovoid, one side often indented; fine chromatin if mature, coarse in young cells and with nucleolus prominent. Occasional binuclear	Abundant acid or basic. Some ameboid activity	Increased				Tend to invade veins, arteries
Hodgkin's Sarcoma form is mostly histio-cytes	18 to 30 micra	Variable cell mixture, lymphocytes, reticulum and plasma; some eosinophiles, polymorphonuclears Always Reed-Sternberg cells 10 to 40 micra. Pleomorphic nucleus, sometimes lobulated, multinuclear cells. Chromatin in large clumps and common nucleoli	Fine reticulated cytoplasm, acid or basic	Increased Common		Usual (except paragranuloma type)	Loss of nodal architecture (limited extent in paragranuloma)	Paragranuloma not invasive. Granuloma may change over to sarcoma
Plasma-cytoma	1 to 12 micra Polygonal or triangular outline	Round, eccentric, heavy chromatin masses at periphery	Basophilic	Not increased	Common	Rare	May remain local for many years	May involve bones and viscera

are reported in this series. Their site classification may be seen in Table 3. In the grand total of lymphoma patients the percentage of involvement of the eye is 4.0. These patients were referred by an active clinic especially interested in this disease. In a recent study of 288 patients at the Massachusetts General Hospital Lymphoma Clinic, 1.7 percent were classified as presenting lymphoma in the orbital adnexas.

Graph 1 shows the age and incidence of all lymphomas in this series and separately those of the conjunctiva, and thus permits a comparison.

TREATMENT

The treatments usually employed for the lymphomas are: surgical extirpation and roentgen ray, or both. Lymphoma tissue is by and large susceptible to small dosage of

TABLE 3
CLASSIFICATION OF CASES

Site	Number	Site %	Cell Types			
			Lymphocyte	Lympho-blast	Plasma	Reticulum Cell
Conjunctiva	30	44.7	20 Giant follicle 1	5	1	3
Lid	13	19.4	5	7		1
Lacrimal gland	2	2.9	1	1

Globe	3	4.4	2		Lymphatic leukemia 1	
Orbit	14	20.8	8	5	1	
Combined site	4	5.9	3 Giant follicle 1			

In the McGavic[4] series of 21 cases, lymphoma accounted for 2.6 percent of the extrabulbar tumors, and Rones[11] found only 19 lymphomas in 11,500 ocular specimens of all kinds of diseases at the Army Medical Museum, and of these, three, or 0.025 percent involved the conjunctiva. At the Massachusetts Eye and Ear Infirmary Eye Pathology Laboratory, lymphomas of the conjunctiva represented 1.8 percent and lymphomas of the orbit 0.84 percent from approximately 1,671 tumors of all kinds and types, original in the ocular adnexa. These comparisons may be seen in Table 3.

In the conjunctival lymphomas, correlation of age, cytology and the aftermath of treatment may be seen in Table 4.

X rays. The usual technique of treatment in recent years (Massachusetts General Hospital) has been 200 kv., 20 cm. object-target distance, $\frac{1}{4}$ mm. copper filter, and daily doses of 200 to 300 r directed onto the conjunctiva for a total of 600 to 900 r. This has not resulted in any untoward effect upon the eye, immediate or remote. (One eye with an orbital lymphoma, not included in the present study, which received 1,200 r has developed an opacity of the lens five years after treatment.) The more scirrhous a lymphoid lesion, as in Mikulicz's disease, the less susceptibility is present. X ray sensitivity is variable enough to be used as a differentiating agent in diagnosis.

Excision is also recognized as good treat-

ment of conjunctival lymphomas. The lid and orbit growth may be treated both surgically and with X ray, dependent upon size and location. The aim may well be: (1) Complete surgical removal; (2) microscopic examination of the specimen; (3) further

Graph 1 (Heath). Age incidence of conjunctival lymphomas versus other ocular lymphomas.

treatment by surgery and X ray, or only by X ray as indicated by the nature of the site, size, and microscopic examination in the pathology laboratory.

The effects of various treatments in this series, other than the conjunctival, are difficult to classify accurately, because of the gaps in the follow-up history. We may say in general that those patients who have an involvement of the eye as a part of a generalized lymphoma have an average outside prognosis of two years. The local ocular treatment, however, has usually prevented recurrent involvement of the eye itself, even when extension has occurred elsewhere.

This is true even when the eye and adnexa were secondarily involved by extension. When the disease is localized, as in the conjunctival group, a remission may be sufficiently long to carry the patient through his usual age expectancy. In two cases in the conjunctival series the patient was untreated for four years. One is alive and one is dead. It just happens that in our series there have been no leukemic blood changes in the conjunctival lesions alone. This agrees with the reports of others (McGavic,[4] Rones,[11] Verhoeff,[12] and Bedell[13]).

SUMMARY AND CONCLUSIONS

The most common cytology in this series is the lymphocytoma. There are noted, however, other cell types, that is, lymphoblastoma, reticulum cell, and plasma cell. Prognosis is not materially altered by cell type. The lymphomas occur more often in the first decade and after the fifth. They respond to X-ray treatment in small doses and to excision when size permits. Long periods of remission may follow treatments. Lymphomas of the lid and orbit are like those elsewhere. If early, small, discrete, and primary, the immediate effects of removal and X-ray therapy are good, the remote poor.

The conjunctival part of this series offers similar findings to that group of lymphomas reported before by Schulz and Heath,[14] namely, that the primary lymphomas of the orbit and conjunctiva are rare and were responsible for less than one percent of a total group of 1,671 ocular tumors. The primary conjunctival lymphomas are relatively benign, if there has been no extension of the process at the time of treatment. A long interval may elapse before general involvement takes place. If the conjunctival lesion is extending and sarcomatous, the prognosis is—in time invariably fatal.

FUSIONAL VERGENCE*

EDWIN FORBES TAIT, M.D.
Norristown, Pennsylvania

It has long been recognized that ocular comfort and visual efficiency in individuals with binocular vision depend not only upon the neutralization of refractive errors, if present, but also upon the precision with which the visual axes of the two eyes can be directed toward the object of regard. While binocular fixation deficiencies are by no means as common as refractive errors, they are frequently the major cause of difficulty in a large proportion of the groups of individuals who are collectively considered as refraction problem cases.

Considerable attention has been given to the development of methods for measuring, designating, and classifying the end effects upon the extraocular muscles of the stimulus-response mechanisms concerned with binocular vision. The various forms of heterophoria and heterotropia have been familiar to every ophthalmologist since the time of Stevens[1] and Maddox. Relatively little work, however, has been done on the

identification and classification of the stimuli which, through the operation of reflex arcs, produce the binocular ocular rotations as responses to the various stimuli.

The present paper reports one of a series of studies on the stimulus-response mechanisms in these ocular vergences.

Although Donders,[2] in his epoch-making classic on refraction and accommodation of the eye, was the first to point out the necessity of coördinated accommodation and convergence in binocular vision, and Helmholtz,[3] a few years later, reaffirmed and amplified his viewpoint, it was not until Maddox,[4] presented the results of his studies of convergence that the importance of the afferent side of the stimulus-response process was recognized. Maddox, however, was unable to develop his concepts fully, as he lacked the essential understanding of the reciprocal innervation-inhibition of opposing muscle groups, which was supplied some years later in Sherrington's[5] work on the integrative action of the nervous system.[5]

In 1917, Sheard[6] amplified Maddox's ideas, and presented a report on a study of the three reflexes then considered to be re-

sponsible for binocular fixation. These were designated as tonic convergence, accommodative convergence, and reflex or fusional convergence. A few years later, a fourth stimulus for convergence was added, that of proximity, or the sense of nearness, and the convergence resulting from that stimulus has been designated as proximal convergence.

Ophthalmic literature is singularly barren in statistical studies showing the distribution and range of these functions. This is probably due to the general acceptance of some widely held but, unfortunately, inaccurate ideas as to the meaning of the results obtained by the binocular balance tests. In many quarters heterophoria is still considered to be an expression of the strength of opposing muscles, rather than the result of faulty reciprocal innervation to those muscles. Again, prism convergence or divergence tests are thought to indicate muscle strength and they are often considered to be faulty when the relationship between prism convergence and prism divergence is not three to one, respectively. Other workers are much distressed if an apparent excessive exophoria at near is found.

In 1942, the Dartmouth group[7] presented the results of a survey of the ocular functions of a large number of students in the course of a study of the influence of visual factors upon motivation. Included in this survey are the results of tests of prism convergence and divergence and reversion to fusion, and the values agree fairly well with those found in the present study. The conclusions as to the meaning and use of the data, however, vary widely from those presented herein.

The distribution of the results in the present study and an interpretation of the facts presented in other investigations of convergence indicate that the vergence functions are the result of reflex conditioning, such as is encountered in any learning process. The conclusions of Chavasse[8] support this concept.

The present report is concerned with the range of modifications in the position of the visual axes of the two eyes, relative to each other, occurring as the result of the efforts of the individual to retain, or to gain, single binocular vision. These efforts may be collectively known as fusional vergence, or, more precisely, as fusional convergence or fusional divergence, supra- or infravergence and cyclovergence.

While the data upon all of these fusional processes has been obtained in several thousand individual studies, from which the 500 considered in this report were drawn, because of limitation of time and space only the lateral vergences, relative to distance fixation, will be presented.

Investigative work in accommodation and convergence must be confined largely to statistical studies of fairly large selected groups, or to intensive studies of the accommodation and convergence reactions of single individuals. Both types of inquiry are necessary for the advancement of knowledge in this field, with perhaps the former being the more applicable to correlation with clinical observation and diagnosis. Animal experimentation can obviously contribute little, as clear single binocular vision, or its absence, can be determined only by subjective reports.

The fusional process, sometimes called the fusion faculty, or simply fusion, is a two fold entity. It is generally considered to be not only the anatomic and physiologic arrangement which permits the superimposition in the visual cortex of the sensory impulses arising in the two retinas, thus making possible single binocular vision and stereopsis, but also a stimulus-response mechanism whose duty it is to keep the object of regard on the proper corresponding retinal points or areas by means of reflex control of the extraocular muscles.

The first function of the fusional process, as outlined above, is concerned entirely with sensory perception and is that which should properly be designated as "fusion." All

cases reported in this study have good single binocular vision and stereopsis and thus have normal sensory fusion.

The second function of the fusional process, that in which there is a varying of the position of the visual axes of the eyes in order to retain or gain single binocular vision, should be considered as fusional vergence.

While these two functions are interrelated and interdependent, only the second will be considered in this paper.

Fusional vergence may be defined, therefore, as a modification produced by the fusional process in the distribution of tonic reciprocal innervation to the extraocular muscles, in order to preserve or to gain single binocular vision.

Fusional vergence, through the years, has been variously known as positive and negative fusional convergence, binocular adduction and abduction, prism convergence and divergence, ability to overcome prism, and prism vergence. Although the terms "adduction" and "abduction," originally introduced by von Graefe as a designation for the fusional convergence and divergence, are convenient, in recent years some writers have confused binocular and monocular duction terminology, so that it is probably desirable to use the more descriptive and accurate general designation of fusional vergence, which term can further be modified by describing the means, such as prism, or haploscope, used in the determination.

In all such studies, it should be kept in mind that the values obtained are relative to the means employed in the study and to the stimulus conditions. Thus a study of the fusional reflexes with prisms, and with stimulus objects of given intensity and at certain distances, would differ somewhat from fusional values obtained by the use of movable stereoscopic apparatus, such as a haploscope. In any type of investigative or clinical procedure, the normal distribution, with respect to the circumstances of the test, must first

be ascertained, after which departures from the usual value can be recognized and evaluated. In the present study, an effort is made to determine the normal distribution of values of the lateral vergence reflexes under certain rigidly controlled conditions.

The 500 cases reported in this paper were taken at random from a much larger group of individuals who have clear, comfortable, and efficient single binocular vision and who were wearing suitable glasses, if they were needed. The only limitation to selection was that, for convenience, only subjects with less than 2^Δ of esophoria or exophoria were included. When lateral heterophoria of greater amount is present, it becomes necessary to calculate the fusional vergence amplitude by including a correction for the esophoria or exophoria. Such cases, however, introduce an additional factor in comfortable vision, that of the constant presence of a considerable amount of fusional vergence effort necessary to maintain single binocular vision for distance, and these patients will be given separate consideration in a later paper.

In the series of procedures used in the present investigation, the object was a 6/30 letter, black on translucent base, and illuminated from behind with an illumination equal to 10 foot-candles at the plane of the letter. The prism values, base-in and base-out, were supplied by means of the Risley prisms in a standard phorometer. In the prism convergence break tests, prism power was increased before each eye simultaneously, making an effort to keep the increase equal in the two eyes, and with a speed of about 4^Δ per second. No attention was paid to the blurring of the stimulus object, but the prism dioptry value just before the patient reported that the object separated into two was recorded. At the speed of increase already noted, this procedure permitted an ample allowance for reaction time in practically all cases. Inasmuch as the accuracy in reading the Risley prisms is somewhat less than 1^Δ when both prisms are used, the

value obtained in the test was recorded in the distribution in the next lowest group. Thus, the two chief variables, the patient's reaction time and the experimental variations in reading the prism calibrations, were compensated for reasonably well.

The same procedure was carried through in the prism divergence test, except that the prisms were increased in the base-in direction.

After the prism convergence value was

TABLE 1

PRISM CONVERGENCE: DISTRIBUTION OF 500 CASES OF ADULTS OF PRESBYOPIC AGE

Prism Dioptries	Break	Reversion to Fusion
2–4	0	204
6–8	20	167
10–12	121	71
14–16	107	38
18–20	126	10
22–24	58	6
26–28	22	4
30–32	26	0
34–36	10	0
38–40	10	0

Values recorded in next lowest prism dioptry group.

obtained by the break-point test, the patient, of course, had diplopia and, in nearly all cases, seemed to fix with one eye, probably the dominant eye. In the remaining few, there was alternation of the eyes in macular fixation of the object. With the patient observing the diplopic images, the prism base-out power in the prism convergence test was gradually decreased at a somewhat slower rate than it had been increased, and the patient was encouraged to tell just as soon as he could see one object only. As soon as he reported that the two images had fused into one, the value was noted, and the value recorded in the next lower group, in order to allow for the errors already discussed.

The same procedure was carried through in the prism divergence reversion to fusion test. In each case, the results represent the average of at least three trials. It was rare,

however, for several trials to vary more than 2^Δ. In other words, the tests are satisfactorily repeatable.

Table 1 shows the distribution of these 500 cases on the prism convergence break and reversion to fusion tests. Table 2 presents the data obtained in the same group of cases in the prism divergence break and reversion to fusion tests. Figure 1 presents the percentage of subjects who failed to maintain fusion in each group during the prism convergence break tests. The reversion to fusion line in the prism convergence graph represents the percentage in each group who failed to obtain fusion as the prism power is reduced. Figure 2 presents the same data relative to the prism divergence break and reversion to fusion tests.

These data show that in a group of 500 subjects, as prism convergence is increased, more persons will fail to maintain fusion. At 26^Δ to 28^Δ only 10 percent can still maintain fusion. Of these few, some can overcome as much as 38^Δ to 40^Δ. The midpoint of the range is about 18^Δ to 20^Δ. In other words, about half the patients could overcome as much as 18^Δ to 20^Δ of prism conver-

18–20	47	0
22–24	3	0

Values recorded in next lowest prism dioptry group.

gence and still maintain fusion.

With prism divergence, half of the subjects cannot maintain fusion with as much as 12^Δ to 14^Δ. Ten percent can go as far as 18^Δ to 20^Δ. Some can go as far as 22^Δ to 24^Δ.

After the break and consequent diplopia, the prism power is reduced until eventually
Fig. 1 (Tait). Prism convergence (500 subjects).
Fig. 2 (Tait). Prism divergence (500 subjects).

the fusion is regained. This occurred in all cases before the prism power was reduced to zero. Apparently the act of stimulating an area outside of the immediate perimacular area with an image similar to that stimulating the other macula (of the fixing eye) results in a change of fixation and rever-

THE EXTRA-MACULAR FUSION AREA OF THE RETINA

of the retina.

sion to fusion. The probability of this reversion increases as the prism power approaches zero. With prism convergence, over 10 percent of the patients will regain fusion when 10^Δ to 12^Δ remain, and 100 percent have regained fusion at 2^Δ to 4^Δ.

With prism divergence, the extramacular fusion area is apparently smaller. Twenty percent have regained fusion at 6^Δ to 8^Δ, 50 percent require the prism to be reduced to, at most, 4^Δ to 6^Δ, and the remaining 30 percent require the prism to be reduced to 2^Δ to 4^Δ to regain binocular fusion.

From the standpoint of the stimulus-

response mechanism in fusional vergence, the data suggest that in the amplitude determinations, the response of the extraocular muscles is dependent primarily upon the stimulation of receptors which immediately encircle the macular area. If, for example, in distance fixation, one eye tends to deviate from the object of regard as the result of the presence of an underlying tonic convergence abnormality for that fixation, these perimacular receptors are stimulated by the image edging over from the macular area and, as a consequence of a probably quite complex associative linking, the tonus of the extraocular muscles is modified and the macula is again brought under the image.

When this process has been carried as far as possible, however, which, from the physiologic standpoint, probably represents the point at which no additional receptors are available, fusion is broken and the eye quickly moves back to somewhere near the primary position, and diplopia is produced. In this situation, the subject fixes the stimulus object with the macula of one eye and, in the other eye, the retinal image is in one of the peripheral fields.

As the prism power is gradually reduced, the image in the periphery approaches closer and closer to the macula in its eye until it finally reaches a point in the peripheral retina where the number of sensitized receptors is great enough, or where there is a synaptical connection effective enough, to actuate the fusional vergence reflex, with the result that the tonus of the extraocular muscles is immediately modified, the eye shifted for macular perception and single binocular vision regained. Thus it becomes possible to plot in a given individual the area on each retina within which images must fall, if there is to be single binocular vision. I have termed this area the "extramacular fusion area." It is shown graphically in Figure 3.

Disregarding the intermediate centers and tracts concerned in these reflexes, which can safely be done in an investigation with an objective such as the present study, we may

consider the perimacular and extramacular receptors and the ocular movements which result from their excitation, as the essential part of the stimulus-response mechanism which is charged with the maintenance of single binocular vision.

As far as the retinal receptors are concerned, it is uncertain whether those concerned in the fusional vergence reflex are rods or cones, or both, and for the present purpose it is immaterial, although the greater number in the perimacular area, as compared to the lesser number in the periphery, and the fact that the process is intimately connected with central vision, would suggest that the receptors are probably cones.

Although not presented in this study, the supra- and infravergence and reversions to fusion may also be obtained and the perimacular and extramacular fusion-area values determined in a vertical direction.

The practical clinical use of the procedures and data presented is beginning to be appreciated by those who are concerned with the abnormalities of binocular vision. The study of presumably normal individuals, at least those with apparent ocular efficiency and comfort, is necessary, in order to provide a precise knowledge of the range of normal variation. With a knowledge of the normal distribution and characteristics, the abnormal cases can then be studied, the faulty stimulus-response systems determined, and an intelligent attack planned to correct the difficulty.

The direct application of the stimulus-response mechanism, as discussed in this paper, to faulty binocular balance situations can be illustrated by the employment of the use-amplitude fraction. The fusional vergence function has, as its chief duty, the securing of single binocular vision and fusion in cases where the individual does not happen to be orthophoric for the fixation distance.

If he is other than orthophoric for this given fixation distance, the binocular images are held upon the two maculas only by the repeated and frequent stimulation of the perimacular fusional receptors, already discussed. If the need of such compensation is determined by a measurement of the heterophoria at the fixation point, the efficiency of the perimacular receptors in providing for its constant neutralization can be obtained by measuring the fusional vergence at that same point and in the proper direction.

For example, if the patient has 4^Δ of exophoria relative to his fixation at 6 meters, he has constant repeated stimulation of his temporal perimacular receptors on either or both maculas. If he has a sufficient number of receptors, and if they have well-completed synaptical reflex connections with the distribution of motor innervation to the extraocular muscles, the exophoria can be well compensated for and the individual will be comfortable.

If, on the other hand, the efficiency of the temporal perimacular receptors and their reflex pathways is not great enough, discomfort from the convergence effort will ensue. As yet unpublished studies in this connection suggest that the average individual may use from one quarter to one third of his total amplitude of prism vergence in the required direction without particular discomfort. If this amount is exceeded, there is a possibility, or a probability, of discomfort from the convergence situation.

In the case discussed above, let us assume that the prism convergence has been tested and found to be 2^Δ. In such a case, therefore, the fusional convergence required for the constant correction of the exophoria for distance would be 4^Δ, that is, the temporal perimacular receptors would have to be stimulated to that extent constantly. In addition to this, they can overcome 2^Δ prism base-out before diplopia occurs. Thus the amplitude of the positive fusional convergence would be the amount constantly used, 4^Δ, plus the 2^Δ of prism convergence, or a total of 6^Δ. Of this 6^Δ, 4^Δ would have to be used constantly, the use-amplitude fraction would

be 4/6, or considerably more than the one quarter to one third amount which could be used without distress.

The corrective process in such a case then would suggest one of two approaches: first, that an effort be made to lessen the exophoria for distance; or, second, to increase the amplitude of fusional convergence to the point where it could take care of the situation without stress. The third possibility, that of neutralizing the exophoria with a prism base-in, has not been considered, as experience through the years has shown that, in the long run, it would be apt to make the condition worse.

In such cases as that cited, attempts to modify the tonic convergence innervational distribution are generally unproductive, leaving, as the only other feasible alternative, a deliberate effort, by exercise of suitable type, to increase the amount of the positive fusional convergence amplitude.

All binocular balance deficiencies can be diagnosed in terms of the particular stimulus-response mechanisms which are at fault, and diagnosis in terms of these reflexes will permit an intelligent prescription of exercise or other corrective procedure designed to discourage or reinforce the appropriate reflexes.

Summary

The data on prism-convergence and prism-divergence trials in 500 adult clinical subjects has been presented.

These data have been interpreted in terms of the source of the stimuli for the motor responses noted. The function of the perimacular fusional receptors, those immediately surrounding each macula, and the extramacular fusional receptors, those further in the periphery, have been discussed. The data suggests that the function of the perimacular group is to retain fusion when once established, while the function of the extramacular group is to aid in establishing or gaining fusion.

The development of the use-amplitude fraction and its application in the diagnosis of binocular dysfunction is presented.

SURGICAL REPAIR OF NEUROFIBROMATOSIS OF EYELID*

MAX M. KULVIN, M.D.

Hines, Illinois

In the *Virginia Medical Monthly* of November, 1941, and in the second edition of his textbook (1941) Spaeth writes, "Although much has been written about plexiform neuromata from a pathological and histological standpoint, the clinical correction of these cases has been neglected in the literature to an astonishing degree. This may be due to the various anatomical defects present, requiring quite a series of cases before any surgical procedures could be outlined."

After a short discussion of the characteristics of these tumors, Spaeth discusses the treatment he has evolved:

1. Roentgen therapy is of no value.

2. General anesthesia is necessary.

3. Dissection of the tissue, removal of all neoplasm, prevention of unnecessary scarring, and conservation of as much skin, tarsal plate, and hair line as possible is advised. Tissue extending into the orbit should be removed.

4. The skin, when removed, is replaced by a pedicle or sliding flap.

5. Cartilage grafts are frequently necessary as well.

6. Best results are obtained in those cases in which the various surgical procedures have been done with a fair interval of time intervening between each operation. From 2 to 4 years are usually necessary to obtain the best results.

When, in April, 1940, this type of case was seen for the first time at the Veterans Administration Hospital, Hines, Illinois, a search of the various available texts disclosed nothing but generalities in regard to

the treatment. I can, therefore, concur with the statement of Spaeth which appeared the following year. It became necessary to evolve, out of a combination of various operative procedures, something to fit this particular type of disability without attempting a complete removal of the lid. Inasmuch as there was hardly one centimeter of tissue which did not contain numerous tumors, it was not felt desirable to transplant such skin in the form of a flap, since we were not familiar with the reaction of such tissues.

General anesthesia was not considered necessary and was not used. Although our first case required no cartilage graft, the second one did, in a sliding-flap formation.

Each case required a number of operative procedures. The removal of various masses from the temporal region and eyeball necessitated a pause to allow for observation and reëvaluation of the result up to that time. The first case was almost completed in one step, but several small subsequent procedures were necessary before a satisfactory result was obtained.

Eight years later, the second case was carried out in more prudent fashion requiring about six procedures before completion.

ORIGIN AND PATHOLOGY

While it is not the purpose of this paper to discuss the origin and pathology of this disease, a short résumé of the essential features might be of interest. Von Recklinghausen's disease is considered to fall in the group of diseases resulting from developmental abnormalities of the ectoderm and mesoderm. It is a congenital condition, sometimes inherited and sometimes encountered as a familial disease. It is characterized by *tumors of the skin, cutaneous pigmentation,* multiple tumors arising from the sheaths of cranial, spinal, peripheral, and sympathetic nerves, abnormalities in bones, defective de-

velopment of the central nervous system, other developmental abnormalities, and buphthalmos.

Unger finds that this tumor may appear wherever there are nerves. In the skin, it may appear as tumors, or pigmentation in form of café-au-lait spots; in the iris, as brownish pigmented tumors; in the choroid, as a "string of pearls;" and as a plexiform neuroma in the region of the eyes, ears, forehead, and neck. The tumors occur along the vagus, acoustic, trigeminus, and sympathetic nerves.

Penfield and Young state that these tumors are invariably made up of tissue of tangled or reticular structure, described by Antoni as Type B, and sometimes contain areas of true perineural fibroblastoma, described by Antoni as Type A. The tangled areas are evidence of a connective-tissue reaction to that obscure abnormality characteristic of nerve fibers in this disease. They find three types of tissue involved—nerve trunk, meninges, and central-nervous system.

The tangled or reticular tissue constituting the background of all neurofibromas should be considered a connective-tissue and sheath-of-Schwann reaction about the fibers of the nerves. Antoni called this Type B—in which no palisading of nuclei or polarization of cells was present. Type A possesses both characteristics—there is an orderly appearance of long slender fibers with silver staining properties, a palisading of the nuclei produced by an orderly parallel arrangement of the cell nuclei, which are elongated with blunt ends. Some areas resemble the structure of the Wagner-Meissner tactile corpuscles.

The Type-B cells are haphazardly arranged and mucocystic degeneration may be present. The fibers are of the reticular type. Collagen bands are rare—Antoni believes that the Type-B cell represents a degenerative phenomenon, a jellification of Type A.

Throughout the three tissues in which neoplasm appears, there is definite evidence of a hyperplastic reaction of the cells peculiar to those tissues. This indicates, says Penfield, that in von Recklinghausen's disease an irritant or stimulating influence is exerted on various tissues causing hyperplasia. Superimposed on, or subsequent to this effect, is the appearance of neoplastic growth of these cells.

Recent work on the production of tumors by Oertel and Ricker suggests that previous to neoplastic growth of cells there is a stage in which, owing to some neurovascular stimulus, the cells that are destined to become neoplastic undergo a hyperplastic change. A chronic irritant is capable of initiating tumor growth. It may be that the congenital defect in the nervous system is capable of producing the necessary irritation of adjacent tissues, producing hyperplasia and later neoplastic growth.

In none of the tumors can the type cell be said to be embryologically undeveloped. The tumors produced preserve the peculiar characteristics of the connective tissue in question. This speaks in favor of the production of tumors by an irritative process rather than from some embryologic rest.

CASE REPORTS

CASE 1

The first patient, R. C. F., a man, aged 50 years, was admitted to Hines Hospital on April 1, 1940, and discharged on August 5, 1940.

Personal history. He had had the usual childhood diseases. He stated that he was born with a drooping eyelid and that he also had a growth behind the left eye which was discovered when he was eight years old. Nine operations for this growth were performed between 1902 and 1908. From the time he was 15 years old, his eyelid has drooped entirely over the eye and thickened blebs have been there ever since. At birth, he had some nipplelike cysts on various parts of the body and many brown spots all over the body. In 1920 he began to develop wartlike bumps of various sizes over his entire body. The biggest one was the size of a

walnut; the smallest, the size of a match head. The skin was dotted with smaller bumps, like prickly-pear spots. The large ones hurt if pressed, but not otherwise. Generally he felt well.

Physical examination revealed a fairly well-developed, well-nourished white ambulant man who did not appear acutely ill. His

Fig. 1 (Kulvin). *Case 1.* Tumors of the skin and café-au-lait pigmentation.

height was 5 feet 6½ inches; weight 133 pounds. His head was normal in size, but there were many nodules on scalp. A fairly large-sized nodule was present in the mucosa of the left cheek. There were countless nodules all over the body, ranging in size from a few millimeters to as large as a walnut (fig. 1). Hearing tests showed he could hear a conversational voice at 35 feet.

Neurologic examination revealed anesthesia and atrophy of the right leg.

Eye examination. The right eye was negative. The left lid was completely ptotic and was large, pendulous, and thickened,

especially at lid margin. A soft fatlike thickness in a roll-like formation extended from the lateral border of the lid over the zygomatic area. Distended vessels were noted in the skin of the upper lid (fig. 2).

With conspicuous effort, the lid could be elevated, revealing slight conjunctival injection. The fundus was normal. A large con-
Fig. 2 (Kulvin). *Case 1.* Neurofibromatosis of the eyelid before plastic correction (May, 1940).

junctival mass was present on the sclera of left eyeball.

Vision was: R.E., 20/20; L.E., 20/100, correctible to 20/50. The pupils reacted to light and accommodation; the left pupil was smaller than the right.

Diagnosis. Generalized von Recklinghausen's disease, including left eyelid and eyeball. Plastic correction of left upper lid was recommended.

Operative procedure. The procedure carried out followed no recognized pattern, but

D.K.WINTER-48

Fig. 3-1 (Kulvin). *Essential steps in the surgical repair of the lid in Case 1 (figs. 3-1 to 3-6).* The large lipomatous mass in the zygomatic region was removed. The skin was undermined and drawn together and sutured.

was a combination of Hunt-Tansley method with some necessary modifications being added as we continued.
Fig. 3-2 (Kulvin). The upper lid was split, separating the tarsus and mucous membrane from the orbicularis and skin.

First, the large lipomatous mass in the zygomatic region was removed and the skin was undermined and drawn together and sutured (fig. 3-1).

The upper lid was split in the gray line (which was markedly thickened) across its entire length, separating the tarsus and mucous membrane from the orbicularis and skin (fig 3-2). The inner section of the lid was seen to be markedly enlarged and thickened. The thickened mass of tissue lying intermedially was removed as completely as possible. A wedge-shaped piece of tarsus and membrane was mapped out and removed (fig. 3-3) and the edges were approximated with silk beginning up near the fornix and going down to the lid margin (fig. 3-4). After the repair of the inner section, a large redundant skin surface was seen to be
Fig. 3-3 (Kulvin). A wedge-shaped piece of tarsus and membrane was mapped out and removed.

present. A plastic correction of the outer lid surface was now carried out.

An incision was made 3 mm. above the lid margin, extending from each canthus to the midline and leaving a strip of tissue, 4 mm.

wide, between the incisions. The incisions were carried up to the orbital margin just below the hairline perpendicular to each other, and the incision lines were joined (fig. 3-5).

A curved incision joined the outer ex-
Fig. 3-4 (Kulvin). The edges were approximated with silk beginning up near the fornix and going down to the lid margin.

tremity of the incision at the lid margin with the perpendicular incision, making a triangular flap of skin which was removed. The ribbon of skin was dissected down to the lid margin. A double-armed silk suture was carried through the upper end of the ribbon strip. The cut edges were united with silk sutures. A stab incision was made 3 mm. above the eyebrow and tunnelled beneath the eyebrow down to the upper edge of the strip. The ribbon was drawn up by the sutures through the incision in the forehead, cut off flush with the skin, and fastened there by several silk sutures. The incision at the gray line was closed by interrupted silk sutures (fig. 3-6). Hot saline gauze dressings were applied because the skin appeared discolored—rubber drains were inserted for the purpose of continuous saline drip—oil
Fig. 3-5 (Kulvin). The incisions were carried up to the orbital margin just below the hairline, perpendicular to each other, and the incisions were joined.

silk covering was applied over this and the eye bandaged. Sloughing of the epithelium took place, with regeneration by granulation and scar formation. On August 5, 1940, the patient was discharged with the advice that further surgery was needed (fig. 4).

Pathologic report. The pathologic specimen was described by Dr. Robert Schreck,
Fig. 3-6 (Kulvin). Placement of the sutures.

Fig. 4 (Kulvin). *Case 1*. Postoperative
appearance.

as consisting of normal epidermis, beneath
which were numerous, irregularly distribu-
ted, small fibroblasts with a small number of
intercellular collagenous fibers. The nuclei
of the fibroblasts were elongated, small, and
stained lightly. There was no inflammatory
exudate. The fibroblasts surrounded and in-
filtrated the normal glands of the corium and
subcutaneous tissue. The pathologic diagno-
sis was neurofibroma (figs. 5 and 6).

Second operation. The patient was re-
admitted on October 21, 1940, for removal
of a tumor mass involving the left sclera
and extending onto the cornea, well shown
in Figure 7.

On October 29, 1940, the operation was
intended to be an enucleation but, after in-
cising the conjunctiva and laying it back,
the mass was found to be easily shelled
away from its scleral bed and removed. No
infiltration of the sclera was found. The
blood supply to this mass from the inferior
pole of the eyeball was marked.

The specimen as described by Dr. Robert
Schreck consisted of a bundle of young
fibroblasts having small elongated lepto-
chromatic nuclei. A moderate amount of in-
terstitial collagen fibers was present. In a
few spaces there was a tendency to palisad-

ing of the nuclei. The capillaries were quite numerous and lined by young epithelial cells. The tissue was infiltrated with a moderate number of lymphocytes and plasma cells. The diagnosis was neurofibroma with chronic inflammation (figs. 8 and 9).

After a period of convalescence, the mass on the left buccal surface, which to all intents and purposes was also a neurofibroma, was removed (fig. 10).

Microscopic examination revealed a small papillary nodule, with many small and large acini, lined by flattened and cuboidal epithelial cells with uniform nuclei. The

Fig. 10 (Kulvin). Buccal mucosa tumor.
Fig. 11 (Kulvin). Low-power view of section showing (x) many large and small acini. The stroma consists of dense fibrous tissue and a small amount of myxomatous tissue.

Fig. 12 (Kulvin). High-power view of section showing (y) large mucous gland attached to nodule.
Fig. 13 (Kulvin). *Case 1.* Postoperative appearance on October 8, 1945.

stroma consisted of a moderate amount of dense fibrous tissue and a small amount of myxomatous tissue. The capsule of the nodule was thick. Attached to the nodule was a large mucous gland. The diagnosis was mixed tumor of the salivary gland (figs. 11 and 12). Of course this finding, when a neurofibroma was expected, was quite surprising.

A secondary plastic procedure was done. Some redundant tissue on the globe was removed, synechias were severed, and the ectropion which had developed was repaired. He was discharged on December 23, 1940.

Outcome. The patient was re-admitted on August 6, 1945, for a possible retroperitoneal tumor, possibly fibrosarcoma. On operation, a biopsy was taken which revealed fibrosarcoma. Nothing further was done. His lid showed no recurrence of the tumor and cosmetically was satisfactory (fig. 13).

Fig. 15 (Kulvin). *Case 2.* Neurofibromatosis of the left eye before correction (June 18, 1947).

CASE 2

The second case, seen June 9, 1947, presented a somewhat different problem. The patient, B. C. H., a man, aged 30 years, was admitted on that day to Hines Hospital complaining of drooping of the left eyelid for 22 years. He stated that the drooping lid became completely ptosed after a lid operation in 1937. He had had three operations on the upper lid of the left eye between 1937 and 1946 by a private physician. His past general history was negative except for hemorrhoidectomy in September, 1945.

Physical examination on admission showed numerous soft papular elevations of the skin over his abdomen, neck, and chest (fig. 14).

Eye examination. Vision was: R.E., 20/20; L.E., 20/200, correctible with pinhole to 20/40—2.

Right eye. The anterior segment, media, fundus, tactile tension, and ocular movements were normal.

Left eye. Anterior segment, media, and fundus were normal. The left upper lid was markedly thickened and indurated. The lid margin was three times its normal thickness. No tarsal plate could be felt. The lid was completely ptosed and could not be raised except slightly in the nasal angle by an exceptional effort of the frontalis muscle.

The conjunctival surface of the left upper lid had multiple scars adherent to the under-

Fig. 14 (Kulvin). *Case 2.* Tumors of the skin and café-au-lait pigmentation.

lying tissue. Fine bands of connective tissue ran between the bulbar and palpebral tissue in the upper and outer quadrant of the eyeball. There was a marked soft swelling over the loose skin of the left temple extending to the outer canthus of the left eye. The bone underneath the swelling seemed slightly irregular and the temporal fossa seemed deeper on the left side (fig. 15).

Laboratory. X-ray studies of the left orbit

Fig. 16 (Kulvin). *Case 2.* Postoperative appearance on July 17, 1947, after first surgical procedure and removal of plexiform neuroma from temporal region.

and left temporal fossa failed to reveal any evidence of significant bone abnormalities.

Urinalysis, complete blood count, complement-fixation and Wassermann tests, bleeding and coagulation time were all negative.

Course in hospital. A tumor mass of the left upper lid and left temporal region was removed June 28, 1947 (fig. 16). The pathologist, Dr. W. W. McNamara, described new growth made up of spindle cells, forming interlacing bundles and palisading, imitating nerve sheath. The growth was quite

cellular but with moderate amount of intercellular collagen in some areas. Cells grew diffusely resembling the so-called Antoni

Fig. 17 (Kulvin). Low-power view of section showing spindle-cell growth, interlacing bundles, and palisading. Diffuse cell growth resembles so-called Antoni-type tumor.
Fig. 18 (Kulvin). High-power view of same section shown in Figure 17.

type of neurogenic tumor. There was no capsule. The diagnosis was neurofibroma (figs. 17 and 18).

On July 23, 1947, a moderate-sized mass

was removed from the left upper lid. The sections showed spindle cells growing in whorls, fairly well vascularized. The diagnosis was neurofibroma (figs. 19 and 20).

These procedures were all preliminary to

Fig. 19 (Kulvin). Low-power section showing (x) spindle cells growing in whorls and (y) vascular section.
Fig. 20 (Kulvin). High-power view of same section shown in Figure 19.

the next step which consisted of the formation of a new tarsal plate for the upper lid. This was carried out by Dr. H. B. Field in a plastic reconstruction of the left upper lid.·

Operation. A lid spatula was introduced under the upper lid. An incision was made
Fig. 21-1 (Kulvin). *Essential steps in the surgical repair of the upper lid in Case 2 (figs. 21-1 to 21-5).* An incision was made at the white line of the lid margin from the outer to the inner canthus.

at the lid margin, from the inner to the outer canthus, separating the conjunctiva from the remnants of tarsal plate and skin. The incision was extended, by blunt and sharp dissection and up into the region of the lid fold,
Fig. 21-2 (Kulvin). A sliding flap was slid into position across the palpebral fissure and anchored to the conjunctiva.

out by the introduction of a fascia-lata sling.

incision was made at the white line of the lid
margin from the outer to the inner canthus
(fig. 21-1).

The conjunctiva and tarsal plate were
separated from the lid through this incision
but were left at their attachment inferiorly.

This comprised a sliding flap which was
slid into position across the palpebral fissure
and anchored to the conjunctiva of the su-
perior lid at its inferior portion (fig. 21-2).

A continuous No. 1, black silk suture was
introduced 1 cm. temporally to the lateral
canthus, and this was brought into the tarsal
D.K.W.

Fig. 21-5 (Kulvin). Suturing after placement
of fascia-lata sling.

flap from the lower lid, comprising a run-
ning suture between the tarsal plate of the
lower lid and conjunctival flap of the upper
lid. This suture was carried the entire extent
of the flap and emerged 1 cm. nasally to the
nasal canthus and on the side of the nose.

The lid margins were then approximated
by means of three marginal notchings of the
skin proper and mattress sutures were placed
from the inferior lid to the superior lid,
tightly binding these exposed notchings to-
gether, so that complete union of the skin
part of the lids was established at these
three points. Drains were inserted at both

to the point which would be approximately
2 cm. from the lid margin. A similar maneu-
ver was accomplished in the lower lid, and an

lateral and internal canthi. A plastic silk dressing with pressure bandage was placed over this eye (fig. 21-3).

The pathologic examination showed the specimen to be similar to the neurofibromas previously described.

After two months' convalescence the tarsorrhaphy was opened, a slight repair of the lower lid was accomplished and the symblepharon present was released on November 19th.

The completion of the repair of the ptosis was carried out on November 26th with the introduction of a fascia-lata sling by Dr. H. B. Field.

Stage 1. A strip of fascia lata, 4 inches long, was excised from the left thigh.

Stage 2. An incision was made parallel to the upper lid margin of the left eye, 5 mm. from the lash line. A cataract knife was introduced and inserted up through the upper lid extending up to the upper edge of the brow. Two tunnels were prepared (fig. 21-4). The strips of fascia lata were inserted through the tunnels forming a suspension of the lid from the incision just above the lid margin. Both ends of the fascia lata were sutured to the periosteum in the brow region. The skin incisions were closed with black silk. A Buller shield with vaseline was used as an eye dressing (fig. 21-5).

Since some excess fibromatous tissue remained, this was removed January 12, 1948, and the defect was repaired by Dr. James E. Lebensohn. Some redundant bulbar conjunctiva and thickened mucosa were reduced with Ziegler cautery. A repeat cautery was required on February 1, 1948, for the persistent ectropion—this practically disappeared after the punctures. The palpebral
Fig. 22 (Kulvin). *Case 2.* Appearance of patient after completion of surgical procedures.

conjunctiva was greatly thickened and arranged in vertical folds. The lower lid showed a thickened conjunctiva arranged in papillary form (fig. 22).

Manifest refraction showed: R.E., 20/15; L.E., 20/50. There was an esophoria of three diopters for distance and near—and a right hyperphoria of two diopters.

CONCLUSIONS

In conclusion, we are aware that the eye results obtained were not artistically perfect. Unquestionably a cosmetic improvement was obtained, in comparison with the situation as it existed for so many years. In the second case, a readjustment of the fascial sling might be undertaken if no further contraction occurs. It must be remembered, however, that the many previous operative interferences certainly added to the difficulties to be overcome.

OPHTHALMIC MINIATURE

Here is the formula useful in both chalazion and styes. Take frankincense and myrrh, of each, one dram; gum labdanum, alum, Armenian saltpeter, of each one-fourth dram. Mix thoroughly with a sufficiency of lilies and old olive oil, and apply the mixture. If these remedies fail, the lid and tumor must be deeply incised with a round-headed lancet and the chalazion scraped out with a spoon at the end of the sound. When the operative wound is large and deep and the parts flaccid, the lips of the wound should be drawn together in the middle by a suture, after which dust on some yellow powder. When the tumor is on the inner surface of the lid, the latter should be everted and the tumor removed from its inner surface. Then order the eye to be irrigated with warm water.

A SURVEY OF ANTERIOR SEGMENT PHOTOGRAPHY

EDWIN S. WRIGHT, M.D.

Los Angeles, California

At the present there are a number of methods in use for photographing the anterior segment of the eye. In the hands of its proponent each method is undoubtedly capable of producing good photographs. Many are called "simple methods" and some, perhaps, are. But, in general, the enthusiastic clinical photographer has a much greater technical knowledge of photography than the average ophthalmologist and not all methods advocated are equally easy to use. It would, therefore, seem advantageous to review the several methods in general use and to evaluate them with respect to simplicity, economy, general adaptability, and availability. In order adequately to explore the possibilities of the methods and to understand better the problems involved, an elementary knowledge of photographic optics, filters, film, and lighting is desirable. Optics should present no problem to the ophthalmologist, since the same formulas with which he is already familiar are used in spectacles and geometric optics. The other items will be of interest also, since a knowledge of them will improve his photographic technique in general, and materially increase his enjoyment of this fascinating hobby.

A. PHOTOGRAPHIC OPTICS

The basic relationship of object, lens, and image is expressed in the simple formula

$$\frac{1}{F} = \frac{1}{u} + \frac{1}{v}$$

where F equals the focal length of the lens, u equals the object to lens distance, and v equals the lens to film distance.

For practical purposes, u and v are measured at the lens diaphragm, for good lenses are not simple, thin lenses but are combinations of various lens elements often having considerable length to the assembly. Their equivalent plane is usually at the diaphragm.

EXAMPLE

With a certain lens, the distance from lens to film is 6 inches when focused on an object 12 feet away. What is the focal length of the lens?

12 feet = 144 inches

$$\frac{1}{F} = \frac{1}{144} + \frac{1}{6}$$

$$F = 5.76 \text{ inches}$$

The image size is expressed in the formula

$$R = \frac{\text{object size}}{\text{image size}} = \frac{u}{v}$$

where R is the reproduction ratio.

EXAMPLE

A camera is focused on an object 20 inches away. The lens extension is 5 inches. How much will the object be reduced on the film?

$$R = \frac{20}{5} = 4 \text{ times.}$$

If the object is 8 inches high, what will be the image size?

$$4 = \frac{8}{i}$$

Image size = 2 inches.

The power of a lens combination is expressed by

$$P = P_1 + P_2$$

where P_1 equals the power of the photographic lens and P_2 equals the power of the supplemental lens. The distance between the two may be disregarded due to the short distance between them and the relatively long focal lengths.

EXAMPLE

What is the power and focal length of a 50-mm. lens with a supplemental lens of 200-mm. focal length (plus 5 lens)?

$$P = \frac{1,000}{50} + \frac{1,000}{200} = + 25 \text{ lens,}$$

or

$$\frac{1,000}{25} = 40 \text{ mm.}$$

The ratio of the focal length to the diameter of a lens determines its "f" number.
Figs. 1 A and B (Wright). Camera and copy attachment (A) with 35-mm. extension tube and (B) without extension tube.

The speed of a lens is inversely proportional to the square of the "f" number and the exposure required is directly proportional to the square of the "f" number. The amount of light received by the film is the product of the illumination and time of exposure; hence, if the lens speed is doubled, the exposure time is halved. Therefore, if the "f" stop is changed from f:4 to f:8, four times the exposure time must be used.

On the camera, each stop from higher to lower number doubles the amount of exposure of its predecessor. The actual amount of light passing through a lens is less than unity since each glass-air surface in the lens reflects back 5 percent of the light falling upon it. The number of glass-air surfaces in most lenses is 6 or 8, and exposure tables of lens manufacturers compensate for this. The "f" number marked is the proper one to use.

Stray light in lenses occurs from internal reflections at glass-air surfaces and may cause shadows to lighten the picture and cause poor contrast. Worse causes of poor contrast are fingerprints and dust on the lens. Coating of the lenses eliminates "ghosts," flare spots, and stray light. It increases the light transmission but its principal value lies in the fact that it improves contrast.
Fig. 1 C (Wright). Hand flashgun with bracket and two transparent X-ray films with tissue paper (diffuser) in between. This is to protect the patient if bulb shatters. Flashgun is shown resting on camera platform.

The speed of a lens varies with the bellows extension. Since the f number is accurate only when the lens is set for infinity, it is highly important to know the effective aperture when the lens is used for close up work. This is found by the formula

$$\text{Effective Aperture} = \frac{V}{F} \times f$$

where V = lens film distance
F = focal length of lens
f = marked lens aperture

EXAMPLE

A 4-inch lens is focused on an object 20 inches away. If the lens extension is 7 inches and the aperture is f8, what is the effective aperture?

$$EA = \frac{7}{4} \times 8 = f14$$

(To measure the lens extension, measure the amount it moves forward from the infinity mark and add it to the focal length.)
Fig. 2 A (Wright). Black and white copy of Kodachrome showing full face when using no extension tube.

Fig. 2 B (Wright). Black and white copy of Kodachrome showing use of 11-mm. extension tube.

If a supplemental lens is used to bring near objects into focus instead of a lens extension, then the "f" number does not change *provided the lens is set for infinity.* The exposure correction can be computed directly from the formula

$$E = E_1 \times \frac{v^2}{f^2}$$

where E = correct exposure
E_1 = indicated exposure (by meter, and so forth)
v = lens film distance
f = focal length of lens

To avoid computations, the *Effective Lens Aperture Kodaguide* may be purchased for 10 cents and automatically performs them.

Figs. 2 C and D (Wright). Black and white copy of Kodachrome photomicrograph, using same apparatus as in 2 A and B. (C) Anterior synechia. (D) Diabetic retinopathy.

Fig. 3 (Wright). Ziegler cautery for entropion (from a color transparency).

Supplemental lenses are weak meniscus lenses which are used to focus the object closer and enlarge the image. A plus supplemental lens shortens the focal length; whereas, a minus lens lengthens it, and, therefore, requires a longer bellows extension. Both enlarge the image.

A supplemental lens attached to a camera focused at infinity will focus the camera on a plane whose distance from the camera is equal to the focal length of the supplemental lens used.

EXAMPLE

A plus 5D. lens will focus an infinity-set camera at 8 inches. Spectacle (meniscus)

Fig. 4 (Wright). Vernal catarrh.

lenses obtained from the optician are quite satisfactory in lower powers. Camera lens corrections are not upset by the supplemental lens (except for negligible chromatic aberration) when the supplemental lens is used with the camera set for infinity. To find the magnification caused by the additional lens, the formula is

$$Ratio = \frac{V}{U}$$

where V equals camera lens-film distance and U equals supplementary lens-object distance

50-mm. lens
200-mm. supplemental lens

$$R = \frac{50}{200} \text{ or } \frac{1}{4} \text{ the size.}$$

The depth of field is that area on each side of the focused plane which will appear acceptably sharp in the picture. It varies according to the focal length, f-number of the lens, lens-subject distance, and acceptable degree of sharpness (circle of confusion). In general, the smaller the focal length and the f-number, the greater is the depth of field. A general rule is that a lens performs best at one half its maximum aperture (twice its f-number).

Correct viewing distance aids in perspective. The picture should be viewed from the center of perspective, which is the point originally occupied by the camera lens. Only so will the relative angular dimensions be correctly reproduced. A small transparency viewed through a magnifier having a focal length equal to the taking lens suddenly acquires an enormous improvement in naturalness. A picture taken with a 5-inch lens and enlarged three times should be viewed at 15 inches and thereby appears more realistic. Pictures projected on a screen should be viewed at the projector-screen distance times the ratio of camera lens-focal length to projector-focal length. Departure from this relation by more than twice markedly reduces the realistic reproduction.

B. Filters

Filters are transparent pieces of colored glass, or gelatin between glass, mounted so that they can be attached to the camera lens. In ophthalmic photography they are used, when necessary, to enhance certain color tones (warmth), or convert different light temperatures to the film requirements. They are not always necessary but are specified by the manufacturer of the film whose recommendations should be carefully followed.

is rarely indicated. Only color film can show the details of inflammation, pigmentation, and fine structure. For 35-mm. cameras, Eastman's Kodachrome Type A or Kodachrome, Daylight Type, and Ansco's Daylight or Tungsten film are available. For larger cameras, each company provides sheet film in both daylight and tungsten types. Such film is for positive transparencies. Kodachrome film, either daylight or tungsten type (K828), may be used with an
Fig. 5 (Wright). Suitable types of cameras. (A) Twin-lens reflex. (B) Single-lens reflex. (C) Double extension bellows.

In addition, Polaroid filters may be used to diminish corneal reflections. White light striking a glass surface at an angle of incidence of 57 degrees from the normal is perfectly polarized. This is one of the three ways in which natural light is polarized and the chief one with respect to the cornea. At angles other than 57 degrees the light is partially polarized. The Polaroid filter stops the polarized (glare) light and passes the unpolarized (diffuse) light when it is turned so that the polarizing element has its axis at right angles to the axis of the polarized light. This position is really determined by looking at the cornea through the filter and turning it until the glare disappears. Since the filter stops part of the light, the exposure must be greater (roughly, one full stop).

C. Film

The advantages of color photography are so great that the use of black and white film

adapter in larger cameras to obtain the economy of small-size film and positive transparency. In addition, roll film may be used although Kodacolor is a negative transparency. Preference for one or the other is an individual matter.

D. Lighting

There are several methods. One is the use of flood lights of the recommended color temperature for the film in use. This method can produce good pictures but has many disadvantages, namely, excessive heat, glare, and bulkiness. Moreover, a child will not readily tolerate the discomfort, and various switches are needed to focus in dim light and then turn on full brilliance for the picture.

A second method is the use of a projector lamp (that is, a T10) enclosed in a tube. This can be combined with a camera shutter to give just the right exposure time but is also bulky and requires an extra focusing
Fig. 6 (Wright). Congenital coloboma of iris (from a color transparency taken with a single-lens reflex camera).

light. It is not so suitable for full face. It may require a filter to convert to the correct color temperature.

A third method is the use of flash bulbs. This includes stroboscopic flash bulbs. This method entails some expense for each bulb but is virtually fool-proof. Provided the camera setting is proper, a good picture is obtained with every exposure. There are suitable bulbs for each film. The Speed Midget bulb with a time of exposure of 1/200 seconds gives adequate light, stops motion of the eye, and requires no filter with Kodachrome, tungsten type film. Used with an f:2.8 lens (50-mm. focal length) with a 35-mm. extension tube, an aperture of f:8 for brown eyes and f:11 for blue eyes has proved satisfactory when the lamp is held at 14 to 16 inches. One test roll will quickly establish the optimum for the combination used. With Ansco tungsten film, a filter is necessary to eliminate excessive blueness; with Kodachrome tungsten film, no filter is required. With daylight type film and blue bulbs, no filter is required.

E. The camera

The problem is the conversion of a lens system whose near point is 3 to 4 feet to a system that will focus at 6 to 8 inches. The most universally used cameras are those of the miniature type. They have short focal length, speedy, highly corrected lenses, are compact, and have a wide variety of auxil-

iary lenses and other equipment. In addition, their transparencies are readily projected and make excellent slides. They range in size from 35 mm. to 2¼ by 3¼-inch machines.

There are two general types. One employs an eye level or split-field rangefinder, that is, the Leica, Contax, Clarus, Argus, and so forth. To adapt these for eye photography a copy attachment is used, and focusing is done with the ground glass of the copy attachment after which the camera is slid into place and the picture made. The camera is focused with the lens wide open and the lens must be stopped-down prior to releasing the shutter. This method is slow and involves many steps but for the owner of this type of camera it is perfectly satisfactory in results.

The second type is a single lens reflex camera. Here, focusing is done through the taking lens, with the ground glass already in the camera. Either a supplementary lens or an extension tube is used for the close up, just as in the previous system, except that here focusing requires only one step. The lens must be stopped down after focusing prior to releasing the shutter. This method is considerably faster than the preceding one. Examples of such cameras are the Exacta, Graflex, Korelle, and Praktiflex. The Graflex has an automatic stop-down which enables wide open focusing and automatic stop-down on snapping the picture. It is the simplest of all.

A third method is the use of a twin-lens reflex camera such as Rolleiflex, Ciroflex, Kodak, and so forth. Here the focusing is done directly and no stop-down is required, as the taking lens is simply left at the proper setting (f-stop). This would be ideal except for the problem of parallax. The viewing lens is above the taking lens and for close-up work does not correct for the difference. There are attachments which overcome this; or, after focusing, the camera may be elevated the required distance. To adapt this fine camera for eye work, a +5D. meniscus lens is placed on the lower lens by use of an

adapter ring and a +5D. lens, with a 14-degree (24.5 diopter) prism ground in it, is placed base down in front of the viewing lens. These may be obtained from the optician. With the object at 8 inches, very slight focusing is required and the normal lens setting is used. An 828 film in a proper adapter makes this a precision instrument for fine miniature films. The transparency can be projected in a 35-mm. standard projector. For full-face shots the supplemental lenses are removed and the regular focus at 3½ feet is used.

The fourth method is the use of a camera with a double extension bellows. Focusing is done by viewing through the ground glass at the back of the camera, after which film plate is inserted, lens stopped-down, and picture made. This is a perfectly feasible method but quite slow and subject to blur if the camera is moved while inserting film plate.

With the fast exposure of a flash bulb, elaborate fixation of the patient's head is not necessary. The chin and head rest of the slit-lamp are sufficient, and there is room behind the slitlamp to mount a camera. It takes only a moment to position the patient, focus, and flash the picture. Synchronization is not necessary. Open flash (bulb) is preferable because the distance of the flash gun (held in the hand) can be varied at will. Gener-

Fig. 7 (Wright). Subconjunctival aqueous in an iridencleisis (from a color transparency).

ally, a distance of 14 inches and partly to the side is best. Lighting directly in front of the eye (at the camera) does not give as good texture definition as cross lighting from the side.

SUMMARY

An elementary review of photographic optics is presented. Lighting methods are enumerated, methods of photography of the anterior segment of the eye are detailed, and advantages and disadvantages are set forth. A method of converting any ordinary camera to anterior segment photography is described.

TALC GRANULOMAS OF THE EYE*

G. L. McCormick, M.D., W. L. Macaulay, M.D.,
and G. E. Miller, M.D.

Marshfield, Wisconsin

In 1912 Lambert[6] first demonstrated the ability of foreign-body substances to stimulate the production of giant cells in tissue cultures. Two decades later Antopol[1] called attention to the clinical and pathologic significance of Lycopodium powder granulomas in surgery and suggested that talcum powder was capable of producing the same reaction. Since then, a fair number of reports have appeared in the literature on granulomatous reactions resulting from the accidental introduction of Lycopodium spores or talcum powder into surgical wounds. As a rule, the gloved hand of the operator is the source of contamination. The abdominal cavity has entertained the greatest number of the reported talc granulomas, but this site is by no means exclusive. Other portions of the body where such lesions have been found include the scalp,[5] brain,[4] maxillary sinus,[4] neck,[1] breast,[1] pleura,[10] bladder neck,[1] epididymis,[1] cervix,[8] vagina,[9] rectum,[7] and other regions. To our knowledge a foreign body granuloma of the eye due to talcum powder has not previously been recognized and consequently is worthy of a report in the literature.

CASE REPORT

History. Mrs. C. J., a white woman, aged 32 years, was seen on September 23, 1947, complaining of rapidly growing tumor masses on the temporal and nasal portions of the right eye. She claimed the lesions were first noticed about two weeks before. Their exact duration was unknown, but the patient emphatically denied the possibility of their existence a month previously. In fact, aside from alarm occasioned by the rapid growth of the tumors, the patient was annoyed be-

cause each of her aquaintances, when met, was startled and inquisitive about her eye. There were no subjective symptoms. There was no history of recent injury.

A review of her past history revealed that on August 18, 1933, a right convergent strabismus, originating in early childhood, had been corrected by resection of the right external rectus muscle and partial tenotomy of the right internal rectus muscle. The post-operative course was apparently uneventful; and, to the patient's knowledge, wound healing was not abnormally prolonged. Other incidences in the past history included an appendectomy in 1932, a Neisserian vulvovaginitis and urethritis associated with a Bartholin gland abcess in 1934, and bronchopneumonia in 1941.

Examination of the right eye disclosed smooth, semitranslucent, grayish tumor masses temporally and nasally at the sites of previous muscle surgery (fig. 1). The mass on the temporal side was larger and measured 10 mm. by 4 mm. The other was only slightly smaller. There was slight injection of the adjacent sclera, and telangi-

Fig. 1 (McCormick, Macaulay, and Miller). Showing semitranslucent tumor mass on temporal portion of right eye at site of previous eye muscle surgery.

ectatic vessels coursed over the tumors. The differential diagnosis this time included keloid, sarcoidosis, and lymphoblastoma. The blood and urine were normal. The serologic test for syphilis was negative. There were no lesions of the skin. Roentgenograms of the chest as well as the small bones of the hands and feet revealed no evidence of sarcoidosis.

On September 24, 1947, a biopsy was performed. The pathologic findings were as follows.* "The sections consist of dense fibrous connective tissue in which are embedded nodules of epithelioid cells. A few poorly developed multinuclear giant cells are

Fig. 2 (McCormick, Macaulay, and Miller). Showing typical foreign-body reaction consisting of dense fibrous tissue, epithelioid cells, and a few giant cells. Small crystals (not visible at this magnification) are scattered throughout this section. (×98.)

present. Many of the nodules contain particles of unstainable crystalline material which is birefringent and which in size and shape resembles talc" (figs. 2 and 3).

On October 14, 1947, the conjunctiva was reflected and both masses were surgically excised. The pathologic report was: "The findings in this specimen are similar to those of the previous specimen except there is some lymphocytic infiltrate associated with the epithelioid nodes. The pathologic changes

* We are indebted to Dr. Hermann Pinkus, Monroe, Michigan, for preparation and interpretation of the histologic specimens.

resemble those found in sarcoidosis, but apparently represent a tissue reaction to the foreign crystalline material which is probably talcum powder."

Following surgery, convalescence was un-

Fig. 3 (McCormick, Macaulay, and Miller). This section shows a large giant cell enclosing a talc crystal. (×330.)

eventful and the wounds healed promptly. Follow-up examinations at 2 and 6 months showed no recurrence. A slight roughness persisted at the excision sites.

DISCUSSION

This case is of interest from several standpoints. Although talcum powder has been known to produce foreign-body granulomas in almost all tissues of the body, this is the first recorded case of such a lesion occurring in the eye. There are several reasons why this apparent rarity may be valid. The operative field in ocular surgery is small. The manipulations are minute. Instruments provide accessibility. The possibility of the accidental implantation of talc in eye surgery is considerably more remote than, for example, in abdominal surgery.

On the other hand, missed diagnosis may in some degree account for the rarity of this lesion in the eye. It must be admitted that the medical profession as a whole is still not entirely aware of the dangerous potentialities of talcum powder in surgery. It is known that many talc granulomas found

elsewhere in the body were originally diagnosed as tuberculosis or some other disease, and only after restudy was the true nature of the lesions disclosed. It has been suggested[2] that the granulomatous masses often seen for many weeks at the site of eye muscle surgery might conceivably be foreign-body granulomas due to talc. These lesions should be investigated histologically.

The fact that some of these tumors may assume a sarcoidlike structure microscopically has already been pointed out by German.[5]

A most unusual feature in this case is the prolonged interval (14 years) from the original eye muscle surgery (the year of Antopol's first report) when talc presumably was implanted to the first signs of growth of the granuloma. In analyzing 37 cases of talc granuloma, most of which developed following abdominal operations, Eiseman and others[3] pointed out that the time interval between the original operation and the appearance of symptoms varied from the immediate postoperative period to 10 years. German's patient[5] first developed signs of activity 14 years after the original wound. Lichtman and others[7] reported that a nodule which first appeared in a scar on the forehead 36 years after the original laceration was found microscopically to contain talc. Hence, although one may expect symptoms of talc granuloma to appear in early weeks or months following implantation of the crystals, such is not always the case. The spontaneous appearance of both lesions at the same time is also impressive.

It is interesting to note that in 1945 Chamlin[2] conducted a series of experiments in which he introduced talc into portions of rabbits' eyes. He was prompted by curiosity to learn if a talc granuloma could actually be produced in the eye since none had been reported. The experiments were planned to simulate the accidental introduction of talc during accepted ophthalmic operations, such as trephination of the anterior chamber, iridectomy, and eye muscle surgery. In most cases typical talc granulomas were produced. Chamlin realized that in eye muscle surgery the operative field is widely exposed and vulnerable to talc contamination in contrast to intraocular operations. He intimated that a talc granuloma of the human eye, when discovered, would most likely be at the site of such an operation. His prediction is fulfilled.

SUMMARY

A case is presented in which talc granulomas developed at the sites of eye muscle surgery 14 years after the original operation.

This is apparently the first recorded instance of such a lesion occurring in the eye.

THE HANDLING OF THE AMBLYOPIC PATIENT*

MAYNARD C. WHEELER, M.D.
New York

When Dr. Post asked me to take part in this symposium, it occurred to me that a description of how we handle the amblyopic cases at Vanderbilt Clinic might be of general interest and should provide the basis for discussion.

HISTORY

The history is of particular importance in the handling of the amblyopic patient. It is amazing how many ophthalmologists seem to feel that a history is not work taking, at least if one can judge from many clinic records. The date of onset, while often unreliable, is still worth recording as accurately as possible. There is general agreement that the earlier the squint develops and the greater the proportion of the patient's life it has been present, the longer it will take to restore vision.

It has surprised me that frequently the parents are not sure which eye is turning and frequently will name the wrong one. This may become important when asking for intelligent coöperation in carrying out the treatment. It is vital to know which eye they think turns when surgery is being performed, to avoid a misunderstanding. Usually, however, this information is given reliably. The history of a weak eye in several members of the family is frequently volunteered.

The story of previous treatment should be recorded carefully, with any comments as to the results.

VISION

Anyone who has seen the bizzare and completely fantastic visions written on the clinic charts, in good faith, by trained nurses, will realize that it is not the simple, routine task that it may seem. One must be on guard particularly in children with one poor eye.

The desire to cover up a defect and to make a good score is strong; so that peeking, memorizing, and guessing must be carefully guarded against.

In our clinic, we are satisfied with the results that we get with separate E's mounted on white plastic squares. We know that we get better visions than with the Snellen cards but, as it is the comparison of the two eyes that is really important, this is not a serious criticism. Careful technique will rule out peeking and memory. Guessing can only be detected by an alert examiner.

Most children aged four years, can be taught the "E game" and they love to play it. A recent writer has advised excluding other children, and the parents, from the examining room. I strongly disagree. Watching others play the E game has melted the resistance of many of our children. It shows them how it is done, it gives them confidence in us and probably stimulates them competitively. We find it worth while to have the mother start the little ones at home, although we have not bothered with records of visions taken at home.

It must be apparent to everyone who has worked with these youthful squint cases, that it is not necessary to wait until the vision can be reliably tested to know that the child is amblyopic. If any youngster uses one eye habitually, the deviating eye will surely be amblyopic. With experience one can tell by the expression of the squinting eye, and the child's behavior, when the fixing eye is covered, that it is amblyopic. Conversely, if there is alternation, even in just one field, you can be fairly sure that there will be good vision in both eyes. This information is reliable enough to enable us to proceed with treatment with confidence, as will be discussed later.

REFRACTION

The most interesting feature of the re-

fraction is the inequality in the two eyes. The amblyopic eye is almost always the one with the greater error. If the reverse is true, one should be very suspicious that it is not an amblyopia from disuse. I know of no way to tell how much anisometropia is compatible with binocular single vision, but this must be considered. I am convinced that occlusion is wrong in extreme cases of anisometropia. Aniseikonia may be important as an obstacle to binocular single vision, but our ideas on this are largely theoretical because of the lack of an adequate means for measuring it in squint cases.

FUNDUS EXAMINATION

The necessity of a thorough fundus examination, before occlusion, should be evident. I believe this to the degree that I demand an examination under general anesthesia if the child will not coöperate for at least a satisfactory inspection of the discs and maculas. Recently this belief was strongly reinforced when a five-year-old boy was brought to me with an advanced retinoblastoma in his right eye. Two years previously, this child had been treated with occlusion of his other eye, unsuccessfully.

TYPE OF AMBLYOPIA

The diagnosis of the type of amblyopia is of great interest but this is largely academic because of the young age of most of these patients. I have no quarrel with the writers who classify these cases by means of their scotomas, but I want to treat these children long before these scotomas can be satisfactorily plotted.

The cases with gross pathologic conditions are easily classified. But there is a group with normal-appearing eyes who do not improve after adequate occlusion. I call this "pathologic amblyopia" and visualize some small lesion in the retina or optic nerve, possibly from birth trauma, that cannot be seen with the ophthalmoscope. I know of no way to separate them from the amblyopias of disuse except by a trial period of complete occlusion. If any case fails to show improve-

ment, or the younger ones fail to switch fixation after two months of complete occlusion, I am inclined to call it "pathologic" and abandon further treatment.

DEVIATION

The examination of the deviation, in the presence of amblyopia, raises special problems. I am referring here particularly to those patients who lack reliable fixation in one eye. Of course, the cover test cannot be used. Simple inspection can be of great value, particularly when the observer is apparently not paying more than casual attention to the child. Talking to him, while playing with a toy dog whose eyes light up, may enable the examiner to note the displacement of the corneal reflex in the squinting eye. Using the same toy-light, and considerable patience, the excursions may be elicited.

But here a word of caution is necessary: when trying to bring out abduction of an amblyopic eye, it is very easy to be misled into the conclusion that there is a weakness of the external rectus. The child follows the light with his fixing eye until the bridge of his nose intervenes, then movement in that direction stops. He sees the light just about as clearly with the peripheral retina of the amblyopic eye as he does with the macula, so there is no incentive to abduct it farther. A day or two of occlusion will usually demonstrate his ability to abduct the eye fully.

With the very young patient, this may be all of the information that can be obtained. The angle of deviation must be estimated by the displacement of the corneal reflex, after the method of Hirschberg. This is only an approximation and unsatisfactory, but if that is all that we can get we must proceed.

Soon after the age of two years, in many cases, a prism can be slipped in front of the fixing eye (base out in esotropia) while the patient is watching a light held on the examiner's nose. This will cause a shift in the fixing eye toward the apex of the prism and a corresponding movement of the squinting eye. When the prism is found that corresponds to the angle of the deviation, the

reflex will be centered in the cornea of the amblyopic eye. This is the prism reflex test, described by Krimsky, which I believe to be both the most convenient and the most accurate method for measuring the deviation for "near" in amblyopic cases. I believe that it is proper to assume that the angles Kappa are symmetrical in the two eyes and to make an allowance for this. A vertical deviation can be measured at the same time by placing a vertical prism before the fixing eye with apex in the opposite direction.

The perimeter still offers the best method that I have found for measuring the deviation for distance, in these cases. Unfortunately, our perimeters are not usually conveniently placed for this purpose and I am afraid that most of us get along without distance measurements. Theoretically at least, measurements can be made in the cardinal directions with the perimeter but this offers great difficulties and is probably rarely done. A careful study of the excursions, comparing the two eyes, should be part of every analysis, however.

TREATMENT

There is general agreement, I believe, on the principles of the treatment of amblyopia. The earlier occlusion is instituted, the more quickly will the result be obtained. Frequently a very young child will accept an occluder more readily than an older one. In most cases the important thing is to take time to explain to the mother what is being attempted; how vital it is; and that it will become more difficult with each delay. The mother's coöperation is absolutely necessary and I have rarely failed to get it when the problem was adequately explained. With a few exceptions, occlusion should be begun with an adhesive bandage, worn continuously. As already stated, a trial period of two months is considered adequate to differentiate amblyopia of disuse from the pathologic type. However, after two weeks of satisfactory, complete occlusion, if the eye fails to fix centrally, I am inclined to stop the treatment. Any visual improvement is an indication for continuing occlusion and I favor keeping it up until there is no further gain over 2 to 4 weeks.

There is no fixed point at which the bandage can be abandoned for less drastic measures. This varies with the age, the refractive error, and the season of the year, as well as the progress of the vision. In recent years, I have used the various types of occluders much less and have relied largely on atropine in the fixing eye, and paper on that spectacle lens. Many mothers are able to regulate the use of atropine, putting in a drop when the child starts to look over the glasses, that is every week or 10 days. Once equal vision is achieved, intermittent occlusion, 1 month out of 3, has been the most satisfactory method of maintaining the vision.

A question that is frequently heard is: why all of this bother when the vision usually slips back as soon as the treatment is stopped? True, if no further attention is paid after the original course; but that is not enough. I am well aware of how difficult it is, but we must strive to maintain the vision, by intermittent occlusion, until the child is at least six years old. I cannot prove it, but it is my belief that if the vision slips after this age, and it frequently will, it can be regained later if ever needed.

Another difficult question is: at what age is occlusion no longer effective? Various answers can be found in the literature and there is no doubt that visual improvement has been obtained in individuals, aged 20 years or more. But there is also no doubt that the task becomes increasingly difficult with added years and that the practical obstacles are formidable. Both in my practice and in the clinic, we rarely recommend occlusion after the age of seven years.

I have made no attempt to discuss the part that an orthoptic technician can play in handling these cases as I have not had the benefit of such assistance. There is no doubt that a technician can shorten the treatment period in many instances, and might succeed at times when I have failed. Valuable aid

can also be rendered at home with drawing, coloring, and games that stimulate the desire to see while using the hands. Home movies have always seemed worth while. Maybe this would even be an argument in favor of television.

Occlusion should always be carried out before surgery, if possible. Waiting for surgery causes an undesirable delay. Psychologically, for parents, it works out better. A course of occlusion helps to prepare them for surgery, while on the other hand, after recovering from the emotional upset of an operation, it is human nature to want to forget about the whole thing. Of course, this may not be possible because in the young ones who do not acquire binocular single vision or alternation, intermittent occlusion may be necessary for a long time, but at least the tedious part is out of the way. Another feature that must be mentioned, although I am unable to explain it, is the recurrence of the squint that occurs occasionally during postoperative occlusion. This is not a strict contraindication but should make us proceed with caution.

As soon as the vision has been equalized, or fixation switched, operation is indicated, unless orthoptic exercises are to be employed. Speed is of the greatest importance, here, if one is to take full advantage of the new condition. The eyes should be made as straight as possible in the hope that binocular single vision will be acquired.

When occlusion fails, a cosmetic correction is all that can be hoped for. A surgical undercorrection should be sought because these are the eyes that tend to turn out later.

In an attempt to see what sort of results I was obtaining, I looked over the records of the last 40 patients in my private practice, for whom occlusion had been prescribed. I considered that a serious effort to carry out the treatment had been made in 33. My criteria of success were: (1) In the young children, shifting of fixation to the other eye; (2) improvement of vision to within one line of the other eye. On these criteria, 21 of the 33 cases were successful. The series is too small to make further analysis worth while. No significant difference could be found between the two groups to explain the failures.

Considering the failures, one aspect stands out. I am sure that we have all been impressed by the emotional resistance in the unsuccessful cases. It is not easy to see beyond the intensity of this reaction for the explanation that very possibly is but the normal reaction of a youngster who is forced to have his only useful eye covered. In other words, these obstreperous ones frequently have a pathologic amblyopia and are truly tortured by occlusion. Unfortunately there is no easy way to be sure. Because of this possibility, I tend to give the child the benefit of the doubt.

CONCLUSION

I have tried to select the points that are peculiar to or of special importance in the examination and treatment of children with amblyopia.

DISCUSSION

F. ELIZABETH JACKSON, M.A.

Erie, Pennsylvania

Dr. Wheeler has already discussed very completely and ably the problems presented by the amblyopic patient and procedures in office treatment of this condition. The handling of the amblyopic patient at an orthoptic clinic is merely a relegation of duties to the technician during the early stages of occlusion and visual development. The problems and methods are the same and are met with the same point of view.

The close correlation of the results of visual achievement in Dr. Wheeler's series of 40 cases with those in a group of 50 cases treated at the Erie Orthoptic Clinic would certainly seem to indicate similarity in treatment. In Dr. Wheeler's group, 21 out of 33 cases, or 64 percent, were successfully treated. In the Erie Clinic group, 32 out of 50 cases, or 64 percent, attained 20/30 vision or better which would seem to be comparable to Dr. Wheeler's criteria of success.

Dr. Wheeler mentions the difficulty of maintenance of vision in the amblyopic eye once it is obtained. It is at this point that the orthoptic technician can make her original and most important contribution.

In this same series of 50 cases with original vision of less than 20/50 in the amblyopic eye, the vision developed by occlusion and supplementary exercises was maintained in 21 cases, or 42 percent for a minimum period of six months. Table 1 shows maintenance in relation to highest vision obtained.

MAINTENANCE OF VISION

Further analysis shows that three factors in particular have an important bearing on maintenance of vision: (1) Length of occlusion; (2) conversion to alternation; and (3) development of fusion and parallelism.

LENGTH OF OCCLUSION

An analysis of length of occlusion in this series shows that, in general, best results were obtained in those cases which were occluded for longer periods. The majority of cases were occluded from 4 to 12 months. Maintenance in the 12-month group was 100 percent as compared to 27 percent in the 4-month group.

This might seem to be the solution to our problem except for the coöperational difficulties involved in long occlusion, especially in older children. When the child is first patched and forced to use his amblyopic eye, with vision usually of 20/200, the parent is sufficiently impressed with his obvious visual difficulties to coöperate completely. During early stages where visual development tends to be rapid, the child himself is pleased with his progress. But later, when vision is improved, the patch gets to be an "old story," and when it can come off part time, its partial use is apt to become slipshod. Too often, everyone becomes discouraged, and the original effort is wasted.

The technician who is giving fusion training during this period of partial occlusion is at an advantage. Frequent clinic visits maintain emphasis, if not always interest. Monocular exercises can be assigned for periods when the patch is on, binocular exercises for periods when it is off, thus making the spacing of occlusion logical rather than arbitrary.

CONVERSION TO ALTERNATION

Dr. Wheeler mentions shift in fixation as a criterion of successful treatment. It is indeed, for a patient with amblyopia of long standing may continue to fix with the originally good eye, although, after long occlusion, its vision is lower (for the time being) than that of the amblyopic eye.

When spontaneous alternation of fixation can be developed, no loss of vision occurs after occlusion is discontinued whether or not fusion and parallelism are achieved. It has been our experience that development of such ability is possible only in the very young child where the deviation is necessarily of short duration. Four cases only of the 50 studied became natural alternators after oc-

TABLE 1

MAINTENANCE OF VISION IN RELATION TO HIGHEST VISION OBTAINED*

Highest Vision Obtained	Number of Cases	No. Cases Vision Maintained	Percent Maintained
20/20	4	1	25
20/25	12	4	33
20/30	16	8	50
20/40	7	3	43
20/50	7	5	71

* In those cases in which final vision of 20/50 was obtained, the original vision was 20/100 in 1 case and 20/200 or less in 6 cases.

clusion and orthoptics. Their ages when treatment was begun ranged from 2½ to 4 years. Thus, may I add another reason to Dr. Wheeler's in his insistence upon early occlusion.

DEVELOPMENT OF FUSION AND PARALLELISM

Of the 21 cases in our series who maintained all of their visual improvement, 4 cases (as previously mentioned) achieved alternation, 3 were occluded for 12 months or longer, and 14 attained parallelism with fusion—that is, they developed the ability to hold their eyes straight in daily life and had fusion under some conditions of distance, size of object of regard, and amount of effort involved. Thus it would seem that achievement of parallelism with fusion, whether by surgery, orthoptics, or both, is the largest factor in maintaining vision. There is nothing startling in this finding. Both eyes are being used; disuse is not present; therefore, one would not expect loss of vision.

However, 11 cases did not maintain total visual improvement by achieving parallelism and fusion. Seven cases dropped to 20/50 still maintaining binocular ability; 4 cases dropped to 20/70 or less with loss of parallelism and fusion. In those cases where loss of parallelism and binocular function occurred along with loss of vision, we can conclude that, although possible, fusion required too much effort to become established as a daily habit, or that coöperation and persistence were not equal to the task, or that the case was dismissed prematurely. But in those cases where binocularity remains in spite of visual loss, we must consider the nature of the binocularity present and look for deficiencies in that function. It is apparent that binocularity will insure maintenance of vision at the 20/50 level, but not necessarily above that.

CRITERIA FOR CLASSIFICATION

Criteria for classification of parallelism and fusion were: (1) Phoria only on cover test; (2) fusion on small targets on synopto-

phore at zero setting; (3) fusion on Worth-4 dot; (4) fusion on fixation light with red cover before dominant eye; (5) appreciation of physiologic diplopia.

DEFICIENCIES IN BINOCULARITY

None of the 50 cases studied showed true stereopsis as tested on Keystone diagnostic slides DB6 and DB60. Some of the patients were too young for this test. Many patients were able to fuse synoptophore targets with parallactic displacement, and many gave accurate responses of depth perception. However, we have found that familiarity with the targets may make this possible by monocular criteria, and does not prove the presence of accurate depth perception.

In some cases, although physiologic diplopia was appreciated, indicating the use of both eyes, certain deficiencies appeared. Some patients were unable to localize one or both diplopia images correctly. Frequently, when the images could be properly spaced by movement of the bar to and from the nose, bar-reading remained an impossibility because the bar-image of the amblyopic eye remained solid, although the second shadowy bar was clearly present.

How are we to explain these deficiencies? The most obvious explanation is continuance of suppression of the macular area of the amblyopic eye in spite of peripheral binocularity. This, of course, would preclude stereopsis and explain inability to bar-read.

Another explanation is malprojection of the amblyopic eye. This theory was recently presented by Dr. Lazisch.[1] He believes that "amblyopia ex anopsia is poor vision due to malprojection of the affected eye so that the visual ray is directed eccentrically to the fovea."

Although time has been insufficient to test much of Dr. Lazisch's evidence, some phenomena have appeared during the course of treatment which favor his point of view. Dr. Wheeler mentioned the fact that better vision is obtained when single E's mounted on white squares are used than with Snellen cards. We have found this to be true in-

variably. It also occurs with the use of the Project-O-Scope when any chart letter is exposed singly. The difference in visual acuity when tested by single letter and row of letters varies with the individual tested, but may be as much as four lines.

Another related phenomenon is noted when the examiner stands at the chart and points to the letters. The child will often read correctly and without hesitation the letter next to (usually to the right of) the one pointed out. He will sometimes read two lines further than the correct vision recording in this fashion. This would seem to be a deficiency in fixation or in interpretation of position rather than in acuity itself.

When the amblyopic child is asked to place thumb tacks in the centers of round discs or other geometric figures of varying sizes with the good eye occluded, he will persistently err, and in the same direction—toward the good eye, regardless of the size of the disc. This is interpreted by Dr. Lazisch as evidence of "malprojection of the visual axis," and continued practice in centering as "relearning eye-hand coördination."[2] This phenomenon seems to me to admit of a simpler explanation, namely, directional judgment based on the child's customary monocular usage and coördination of hand with the good eye.

Whatever the explanation, improvement in the patient's ability to center occurs rapidly with daily practice and, although this particular phase of treatment has been tried only recently in our clinic on an experimental basis and with patients whose vision was 20/70 or better, in most cases one line of visual improvement has occurred, and in all cases more stability of fixation has been noted on the synoptophore. It is too soon to judge whether this initial improvement will continue or be maintained.

Whether we explain the binocular de-

ficiences of the amblyopic patient on the basis of macular suppression, malprojection, or a pathologic dominance of the better eye, treatment must be directed toward correction of these deficiencies. They are as much a part of the syndrome as loss of acuity.

Dr. Wheeler has mentioned the use of drawing, coloring, and games that stimulate the desire to see while using the hands. I heartily endorse this procedure and suggest that the element of correct spatial judgment can easily be incorporated into these monocular tasks.

Emphasis in treatment should always be placed on developing ability to fix with the amblopic eye, to alternate fixation at will, and to appreciate diplopia under as many conditions and in as varied visual situations as possible.

Discernment of minute, centrally spaced details with the amblyopic eye should always be insisted upon in training with haploscopic devices. We must aim at the macula to develop acuity. Excellent results in treatment of amblyopia by rhythmic illumination have been reported by Miss Helen Cotter.[3]

I am certain that we have all wondered during the prolonged course of treatment of the amblyope whether our efforts are justified. To persist in treatment in the individual case when no improvement is noted within reasonable limits is certainly futile. We must recognize and accept the variable limitations of the individual case.

Our tabulations of results show 64 percent of cases with satisfactory visual acuity atttainment, maintenance of vision in 42 percent of these, and imperfection in the binocularity of those who attain fusion and parallelism (notably, lack of stereopsis). Although this achievement justifies the effort entailed, still it is a dubious laurel upon which to rest in smug complacency.

NOTES, CASES, INSTRUMENTS

ESSENTIAL (PROGRESSIVE) ATROPHY OF THE IRIS

PAUL WINSLOW TISHER, M.D.
New Britain, Connecticut

Eighteen months ago this patient was examined in the office and showed early signs of essential iris atrophy which was not recognized as such. At that time the vision of each eye was 20/20 with small hyperopic correction, and her main complaint was that of burning, twitching, and tearing of both eyes and some difficulty with close work.
Fig. 1 (Tisher). Essential iris atrophy.

Muscle balance was normal except for convergence weakness.

The left eye showed no change, but the right eye showed a slight tucking effect in the upper nasal area. This appeared as if an injury at the limbus had caused a slight drawing up of the iris into a break in the periphery of the cornea. The patient gave no history of direct injury to the eye, but did mention that she had fallen two years before and had struck her head in the occiptal region with sufficient force to cause loss of consciousness for a short time.

There was no evidence of inflammation either outside or inside the eye. The fundus appeared to be normal. The slitlamp showed no floaters or keratic precipitates, and the iris stroma appeared perfectly normal except for the bunching, drawing up effect at about the 2-o'clock position. Routine perimeter readings were normal and tension was normal to fingers. Glasses were prescribed and the patient was asked to return in one month for reëxamination. There was some doubt concerning the diagnosis, but the findings were noted as probably being the effects of an old injury.

The patient did not return until 18 months later at which time she stated that she had had no difficulty until two months previously when she began to notice spots before the right eye and extreme photophobia. She also had occasional headaches relieved by aspirin.

The findings in the left eye were unchanged but the picture in the right eye was markedly different. Routine examination of fields and fundus showed no changes from the previous examination. The cornea was clear. Finger palpation, however, showed a hard eyeball. Tension at this time was 90 mm. Hg (MacLean). The anterior chamber was deep and the iris was displaced. The pupil was pulled up and irregular so that the lower edge was above the middle; the upper edge was at the limbus. There was a large atrophic hole in the lower portion of the iris about 2.5 mm. in diameter, with some strands, stroma remnants, extending vertically at the temporal edge of the hole. There was an almost equally large area of atrophic stroma temporally and another smaller area in the lower temporal aspect.

The stroma was also atrophic in other areas, the stroma layer being definitely more atrophic than the posterior pigment layer. At the upper limbus and also in the upper temporal aspect of the iris, the root of the iris appeared to be definitely thickened. It almost appeared as if this area in thickening and shrinking had pulled the pupil up and that the pull had caused the opposite portion of the iris to become atrophic.

Repeated doses of miotics of various strengths brought the tension down to be-

tween 50 to 60 mm. Hg (MacLean) and 28 to 32 mm. Hg (Gradle-Schiøtz). This seemed to relieve the patient of pain and ocular difficulty. Discontinuance of the medication caused immediate rise in tension and return of symptoms.

Duke-Elder describes this condition as a unilateral disease of unknown etiology, characterized by a slowly progressive atrophic change in the tissues of the iris, which leads to the complete disappearance of large portions of the tissue and ultimately ends in blindness from absolute glaucoma. He further describes it as coming on in early adult life with the development of an eccentric position of the pupil, which becomes distorted and displaced to the side. Usually the pupil shows an ectropion of the pigment epithelium and, finally, merely a shriveled remnant of the iris connects it to the ciliary body. On the opposite side, large holes appear in the iris. These enlarge and coalesce so that the entire tissue atrophies until only a few strands of stroma remain, with large apertures between. Eventually, after some years, when most of the iris vanishes, the tension rises and the first clinical symptoms become conspicious.

The glaucoma that develops shows little response to miotics and can rarely be operated with success. The common end result is blindness. As far as can be learned, all cases reported have been unilateral.

RETINAL ANGIOSPASM*

The fundus in diffferent stages of an attack in the left eye

Ursula Rexed

Stockholm, Sweden

A number of cases of retinal angiospasm showing attacks of temporary blindness have been described in the literature (Duke-

Elder: Textbook of Ophthalmology, v. 3, 1945). However, it is seldom that such attacks have been photographed. I am showing here a series of photographs of the fundus taken during an attack.

CASE REPORT

History. The patient, a business woman, aged 40 years, had often shown signs of vasolability with blushing, palpitation, and a general sensation of warmth. She had occasionally had a slight feeling of numbness in her fingers, otherwise she had had no symptoms of circulatory disturbances or endocrine trouble. Three years earlier she had had an attack of blindness of the left eye which lasted for 2 to 3 minutes and which did not recur. She had had no more attacks between this time and the time when she was observed at the clinic.

She arrived at the ophthalmic clinic one evening in October, with an acute attack of blindness of the left eye caused by retinal angiospasm. This attack lasted for a couple of minutes and was followed by a series of similar attacks in the left eye, each attack lasting for about 10 minutes. The patient was extremely nervous and agitated and showed palpitation and blushing cheeks.

The pulse rate and blood pressure showed an increase during the attacks. In one attack the pulse rate rose from 104 to 120 and the systolic blood pressure from 130 to 150 mm. Hg.

The visual acuity of the left eye was 0.8 between the attacks and diminished to perception of hand movements during an attack. In the left eye the perimetric field was being measured when an attack occurred. The field was rapidly diminished from without inwards. Between the attacks the field was normal and showed no scotomas.

The patient was given vasodil subcutaneously and by mouth and luminal tablets and put to bed. The attacks continued during the night but had practically ceased by the next morning. Only a couple of stray attacks occurred during the day, one of which was

Fig. 1 (Rexed). The normal fundus of the right eye.
Fig. 2 (Rexed). The normal fundus of the left eye.
Fig. 3 (Rexed). Fundus of the left eye taken between attacks of retinal angiospasm, three hours after a preceding attack and about 10 minutes before the photographs (figs. 4 to 8) of different stages of an attack.

Fig. 4 (Rexed). Fundus of the left eye during an attack of retinal angiospasm taken about one minute after the attack had started. The arteries have contracted, several of the smaller arteries can no longer be seen (the small artery at the 9-o'clock position and the smaller arteries between the 3- to 6-o'clock positions). The veins have also contracted and the color of the fundus is paler than in Figure 3.

the one photographed. After this, no more attacks occurred, although the patient stayed at the clinic for over a week.

A thorough general examination was made of the patient with a view to finding the etiology of the attacks. The electrocardiogram showed a sinus tachycardia with a rate of 120. The arteries of the legs and feet were examined by oscillometry, and the skin

temperature was recorded after vasodilatation. The results seemed to show a certain lability of the arterial tonus.

All other investigations were negative. Heart and lungs were normal. Neurologic examination was normal. Gynecologic exam-
Fig. 5 (Rexed). The arteries are now extremely narrow and this is seen especially upward in the picture. There is a segmentation of the blood column in some of the veins. The color of the fundus has become still paler. (Taken 15 to 20 seconds after Figure 4.)

Fig. 6 (Rexed). A different part of the fundus, showing the macula. On the optic disc the arteries are seen to be empty. This was a phenomenon that occurred toward the end of each attack as the spasm reached its maximum, and which was followed by a sudden filling up of the vessels, as seen in Figure 7. A slight cherry-red contrast is seen in the macula. Ophthalmoscopically, a slight edema was observed. (15 to 20 seconds after Figure 5.)
Fig. 7 (Rexed). In this view, most of the vessels have filled up. Some of the arteries are, however, still empty and are seen near the disc as thin white lines. The veins are engorged. The fundus has started to regain its color, especially in the periphery. (15 to 20 seconds after Figure 6.)
Fig. 8 (Rexed). All of the arteries are now filled up. The veins are still engorged. The fundus is redder. (15 to 20 seconds after Figure 7.)

ination was normal; the patient had never had any disturbances of menstruation. The basal metabolism rate was a plus 11. An electroretinogram, taken between the at- tacks, gave normal findings. It was not possible to provoke an attack during the registration.

AN ELECTRICAL REMOTE CONTROL FOR THE REVOLVING ASTIGMATIC CROSS

HORACE L. WESTON, M.D.

Detroit, Michigan

The revolving astigmatic cross has been recognized for years as a useful aid in the measurement of ocular astigmatism, particularly with regard to the strength of the correcting cylinder. However, since the cross is of little value unless it can be turned to the appropriate axis for each eye, it has been necessary to devise remote controls in order to eliminate the inconvenience of direct hand adjustment.

Remote control has usually been achieved by the use of strings and weights or by the use of a gear box and reversing motor. The former method accomplishes the purpose well but frequently necessitates the use of unsightly strings. The latter method is more modern in appearance but too slow in operation.

For the past year, I have been using an electrical remote control which is practically instantaneous in action and is accurate to within one degree. The astigmatic cross which is mounted near the Snellen test chart is synchronized with the dial on the control box by the use of a pair of selsyn generators. These "generators" or "motors" were obtained from war-surplus stock (frequently advertised in popular science and radio magazines). The motors in use (fig. 1) were

designed to operate on 115 volt-400 cycle A.C. but work well on 24 volt-60 cycle A.C., as obtained from an ordinary furnace control transformer.

The control unit (fig. 2) is mounted in a box on top of which are push-button switches for the primary circuit and for a muscle light. The primary circuit is turned on only when the dial is being rotated, in order to eliminate hum. An 8-wire radio battery cable leads from the control box to the chart box.

In present operation, reverse charts are employed for use with a mirror. For operation at 20 feet one needs only to use a longer cable and to reverse two of the control wires so that the generators will turn in opposite directions. The driving generator and the muscle-light mounting are located behind the face of the box. Storage space for other charts is located in the upper half and is reached through a slot in the side.

In addition to affording an excellent test object for the finer measurement of cylinder strength the single-line cross is useful when used in connection with the cross-cylinder in the highly sensitive axis test reported by Crisp and Stine.* To facilitate this test small marks have been added to the control dial at the 45° and 135° positions.

703 Stroh Building (26).

* Crisp, W. H., and Stine, G. T.: A further, very delicate test for astigmatic axis, using the cross cylinder with an astigmatic dial and without use of letter charts. Am. J. Ophth., 32:1065 (Aug.) 1949.

COLLEGE OF PHYSICIANS OF PHILADELPHIA

SECTION ON OPHTHALMOLOGY

October 21, 1948

DR. PERCE DELONG, *chairman*

OPTOCHIASMATIC ARACHNOIDITIS

DR. MORGAN B. RAIFORD (by invitation) presented an 8-year-old white boy, who was admitted to the Graduate Hospital of the University of Pennsylvania on June 15, 1948.

The chief complaint was that of poor vision in both eyes which was first noted in December, 1947. He had no history of any intercurrent disease, either ophthalmic or systematic other than a fall in October, 1947, which resulted in a contusion of the forehead without any noticeable effects.

When returning to school after the Christmas vacation, he noticed that he was unable to see the blackboard. There was no pain or redness or any other symptom. He was hospitalized from the middle of February to mid-April, 1948. The diagnosis at that time was optic neuritis. He had had spinal-fluid examinations, six typhoid injections, and multiple vitamins. These studies were repeated in another hospital and confirmed. The patient's visual defect gradually increased, however, up to the time of hospitalization (mother's statement) of June of this year. The parents have been in excellent health, and the boy's one sister, is normal.

Systemic review. Tonsils had been removed at five years of age. The patient had complained of transitory frontal headaches that were noticeable by his mother in November and December, 1947. They were dull and diffuse in character. He had suffered with no headaches since that period.

Neck, negative; heart and lungs, negative; appetite good, abdomen and bowel function normal—no history of nausea or vomiting; genito-urinary system, negative; extremities, negative; skin, negative. The patient had no physical abnormalities other than the ocular defects.

Eye examination. There was no exophthalmos, ptosis, nor nystagmus. Pupils were round, central, reacted equally to light and accommodation, and consensually. Tension was: O.D., 17 mm. Hg (Schiøtz); O.S. 19 mm. Hg. Extraocular movements were normal and full. Lids and lacrimal apparatus were normal. Vision was: O.D., 2/60; O.S., 2/60.

Refraction under atropine cycloplegia on June 17, 1948, was: O.D., +0.5D. sph. = 2/60; pinhole, 2/60. O.S., +0.5D. sph. = 2/60; pinhole, 2/60. The patient complained of his vision being smoky.

Visual fields on June 18, 1948, showed concentric contraction of both the peripheral and central fields with slight enlargement of the blind spots. No scotoma was present. Could not see less than 5-mm. white test object clearly. Sclera and cornea were normal; lenses were clear and normal; vitreous was clear.

Fundus examination showed that the discs were pale and both outlines were hazy. A binocular ophthalmoscopic examination was done, and no evidence was present that suggested old papilledema. The blood vessels were normal with an arteriovenous ratio of 2 to 3. The macular areas revealed slight pigmentation. The periphery were clear. No hemorrhages or exudates were present.

A neurologic examination by Dr. Joseph Yaskin did not reveal any other abnormalities.

On June 18, 1948, X-ray studies of the skull, orbits, sella, and optic foramina were negative.

A ventriculo-encephalogram was done June 29, 1948, by Dr. Finkelstein and the following reported: "Only a small portion of the third ventricle is visualized and this is normal in size. The fourth ventricle is not

visualized. No air can be seen in the basal cisterna or the subarachnoid pathways. We are, therefore, unable to exclude the presence of a posterior fossa lesion, such as a tumor or basal arachnoiditis."

Operation. In veiw of these findings, a right frontoparietal craniotomy was done by Dr. Robert A. Groff on July 6, 1948, and a chronic arachnoiditis was found around the optic nerves and chiasm. These fibrous bands and adhesions were incised and the optic nerve freed.

The patient made an uneventful recovery, and was discharged on July 13, 1948.

The patient was last seen on September 15, 1948, at which time the visual acuity was: O.D., 6/30; O.S., 6/7.5. The visual improvement has been quite noticeable to the patient, and he has been able to read without any difficulty.

Discussion. Dr. Robert A. Groff: There is one contribution I should like to make, and that is that there are other cases which have been verified by operation. However, I do not believe there are any so young verified by operation in the literature. Arachnoiditis is a definite entity. It occurs primarily around and near the chiasm, and secondly about the cisterna magna in the posterior fossa, in both instances frequently simulating tumor. This is in the literature, and was referred to by Dr. Frazier as pseudotumor.

The diagnosis is extremely difficult and, to me, is only made at the operating table. I do not believe that the diagnosis can be made clinically with certainty, but it can be suspected, and then confirmed at operation. It is very difficult to make a decision to operate on such an individual, because the operation is rather serious. However, one weighs that against the fact that vision is extremely important to the patient. The entire matter has to be put before the family with the idea that we may be able to do something for the vision of the patient or not, depending on what we find. In this patient we were very fortunate in finding a definitely thickened

arachnoid, which was removed from the region of the chiasm. The subsequent course showed that the arachnoiditis had been the cause of the visual effect.

SECONDARY FUNCTIONS OF INFERIOR OBLIQUE

DR. WILLIAM E. KREWSON, III, briefly reviewed the literature with its confusion regarding the manner in which the inferior oblique muscle moves the eye. Perspective drawings portraying the muscle plane and the location of the muscle were shown for various positions of rotation.

The action generally attributed to the inferior oblique muscle is primarily that of extortion, which increases as the eye is externally rotated, together with the secondary or subsidiary functions of elevation, which increases as the eye is turned inward, and external rotation, which increases as the eye is rotated outward. Based on the anatomic data of Volkmann, variations in these generally accepted actions apparently exist.

Both the primary function of extortion and the subsidiary action of elevation can be shown to have their maximum effect when the eye is turned outward seven degrees, while at this position the horizontal rotating effect is nonexistent. As the eye is turned outward beyond this position, the inferior oblique muscle becomes an external rotator and, as the eye is turned inward from this position, the muscle acts as an internal rotator.

The manner in which the muscle actually functions depends upon its angular attachment to the globe. Probably these opposing views can be reconciled on the basis of the marked variation which is known to exist in the anatomy of the extraocular muscles.

Discussion. Dr. Francis Heed Adler: This careful study by Dr. Krewson is about the best argument we have for abandoning the old conception of a primary, secondary, and tertiary action of each of the ocular muscles. This may have been a convenient way of teaching the various components of

pull of each of the muscles, but it leads to false conceptions.

These studies show that the inferior oblique has one action in one position of gaze, and in another position a diametrically opposite action. The same is true, not only of the inferior oblique, but of the superior oblique and both the superior and inferior recti. We think of the superior rectus as an adductor, and it is, in the primary position of gaze, but, when the eyeball is abducted 23 degrees from the primary position, it loses its adduction as one of the components of its pull, and, when the eye is rotated outward beyond that point, it then becomes an abductor.

I think we must accept the studies that have been made which show that there is no center of rotation of the globe. The studies of Park and Park and of Verrijp and others have proved conclusively that we do not have such ideal conditions as a point center of rotation about which the eye moves.

The eye makes transitory movements laterally, forward and backward, and up and down, and the centers of rotation cover an area of some few millimeters. For this reason, it is extremely difficult to make calculations which decide in just what position the inferior oblique becomes an adductor instead of an abductor.

There is a point in muscle physiology, which is often overlooked, and that is that in all ocular movements, more than one muscle is contracted. In the lateral versions, for example, five muscles are co-contracting in each eye simultaneously. In dextro-version, the lateral rectus of the right eye acts sufficiently as an abductor at the start. In this position it has a long arc of contact, and is working at a mechanical advantage. The superior and inferior recti in this position co-contract, and keep the eyeball from moving up or down. They also act as adductors in this position, but this adduction is balanced by the co-contraction of the two obliques which keep the vertical meridian erect and by their abducting effect counterbalance the adducting effect of the superior and inferior recti. As

the movement progresses, the lateral rectus acts to a greater and greater disadvantage.

When the eyeball has passed 23-degrees abduction, the superior and inferior recti become abductors, and they, together with the obliques, are largely responsible for the further abduction of the eye. This fact explains the modus operandi of the Hummelsheim operation, and probably all operations which are modifications of this. By transplanting part of the superior and inferior recti to the attachment of the lateral rectus, we make these muscles abductors by their co-contraction, and this abduction takes effect at the very beginning of dextro-version.

These studies by Dr. Krewson are of vital interest, and should eradicate from textbooks the idea that each ocular muscle has three separate functions.

Dr. Krewson, (closing): I want to thank Dr. Adler for his informative discussion. His criticisms are well taken, and quite justified. It is true that there is no fixed center of rotation, and that this center is not identical with the anatomic or geometric center of the globe. Also, variations due to the check-ligaments, Tenon's capsule, and the like are factors, but probably none greatly affect the overall picture.

It is also true, as I intended to mention but omitted because of limited time (but will include in published manuscript), that no one muscle acts on the globe independently or at any one time. I did not wish to imply that the muscle, the inferior oblique in this case, actually and independently turned the eye to the positions indicated; rather, the analysis is to show how the energy of the muscle is expended on the globe, or how the muscle really acts, when the eye is already rotated in the various positions mentioned.

SYPHILITIC PRIMARY OPTIC ATROPHY

DR. JOSEPH V. KLAUDER, DR. GEORGE P. MEYER, and DR. BENJAMIN A. GROSS (by invitation) gave a brief resume of the reports on the frequency of syphilis as a cause of blindness. They said that 10 to 15 percent

of blindness is due to syphilis. The importance of this in the United States is shown by the fact that there are between 20,000 and 30,000 cases of blindness due mainly to syphilitic optic atrophy.

A report was presented on the study of 397 cases of syphilitic primary optic atrophy, 20 of which were of congenital syphilitic origin, the remainder acquired. The authors discussed (1) Relationship of age, sex, race, and type of disease; (2) character of antisyphilitic therapy before onset of optic atrophy (treatment was shown to be deplorably inadequate); (3) visual acuity, time of admission to clinic (61 percent were industrially blind or worse); (4) pathogenesis —generally accepted view is the inflammatory origin; (5) symptomatology—stress was laid upon diplopia and leg pains as prodromal, and loss of vision and field changes as early symptoms, accompanying neurosyphilitic signs are also present; (6) diagnosis—probably the earliest sign is a field defect, loss of central acuity and pallor of disc usually occur later and indicate further advanced and usually irrevocable changes.

The authors' comments were: (1) Syphilis is a very frequent cause of blindness, approaching cataract and glaucoma in importance; (2) ophthalmologists are urged to be alert to the early diagnosis of this condition, for early diagnosis holds the only promise of amelioration or arrest.

Discussion. Dr. Joseph V. Klauder: In addition to the rather pessimistic figures presented by Dr. Meyer in the forepart of his presentation, one could make rather similar deductions from the following. Before the war, the incidence of new cases of syphilis in the United States as calculated by the U.S. Public Health Service was about one-half million per year. That decreased until shortly after the war it slightly increased, and it is estimated now that there are about one-fourth million new cases of syphilis arising each year. It is thought that, of new cases of syphilis, about 5 percent, if untreated or inadequately treated, will later develop

tabes dorsalis; of these patients, 10 to 15 percent will develop optic atrophy. This estimation applies only to patients with tabes dorsalis, and does not apply to about 40 percent of patients with optic atrophy associated with neurosyphilis other than the tabetic form.

Dr. Meyer has presented our rather unfortunate experience in early diagnosis of optic atrophy at Wills Hospital. The figures he presented—61 percent of patients when first seen were industrially blind—are certainly not gratifying.

What can we do about it? I think the importance of syphilis as a cause of blindness needs no emphasis. It is worthy of attention of every physician who treats syphilis. The ophthalmologist is particularly concerned in syphilis as a cause of blindness. We appeal to ophthalmologists for more interest in syphilis as a systemic disease, in its public health aspects, its treatment, and in the early diagnosis of optic atrophy. We believe that was the implication in Berens and Goldberg's report (Syphilis in relation to the prevention of blindness: A study of 100,000 case records. J.A.M.A., 109:777-781 (Sept.) 1937) in which it was stated that frequently insufficient attention was given to the history, examination, serologic tests, and treatment of patients whose ocular disease was syphilitic in origin.

Optic atrophy occurs in patients whose neurosyphilis usually pursues a silent form. It is infrequently associated with the classical symptoms of tabes dorsalis—dysuria, ataxia, and severe leg pains. In our study the two most frequent symptoms preceding subjective loss of vision were diplopia and leg pains. Diplopia was usually transitory and preceded, frequently by years, loss of vision. Leg pains were usually mild and elicited only by direct questioning. Optic atrophy predominantly occurs in patients who are unacquainted with their infection and who have had no antisyphilitic treatment. Unfortunately, the major symptom that leads to diagnosis is impaired vision.

Ten years, at least, elapses after infection

for optic atrophy to develop, the usual interval is 18 years. There must be a period in which early perimetric field defects are present preceding pallor of the nervehead and impairment of visual acuity. From our study, we believe that that period may range from a few months to several years. We would stress that interval as a propitious one for early diagnosis of optic atrophy. To accomplish this, routine ophthalmoscopic examination is necessary on every patient with syphilis of more than 10 years' duration, certainly on every patient with neurosyphilis. It is to be recalled that pupillary abnormalities are common symptoms of neurosyphilis, appearing early and constituting "short cut" in clinical diagnosis.

Bruetsch observed basilar meningitis as part of optic atrophy existing in the absence of other evidence of neurosyphilis. Clinical diagnosis of syphilitic optic atrophy is, therefore, justified in a syphilitic patient without evidence of neurosyphilis. In our experience, however, this occurrence is rare.

To facilitate early diagnosis of optic atrophy, ophthalmologists and all physicians who examine patients with syphilis should have a high degree of awareness of the optic nerve. In records of private, ward, and clinic patients, too infrequently no mention is made of examination of the optic nerve unless the patient complained of visual loss. The ophthalmologists are admirably situated to exclude optic atrophy in every patient examined, who has had syphilis of some years' duration, at least in patients with pupillary abnormalities.

The ophthalmoscope and the perimeter should be added to the lists of instruments— dark field microscope, lumbar-puncture needle, roentgen ray, and electrocardiograph —of vital importance in the diagnosis of syphilis.

Dr. Louis Lehrfeld. In the year 1937, there was prepared from data at the Wills Hospital a survey on optic atrophy due to syphilis. This survey covered a period of years, 1926 to 1937 inclusive. There was a total of 522 patients studied. All of these patients had some degree of optic atrophy. It is gratifying indeed to find that the present investigators have found statistics that are quite comparable with those that were reported by me in 1937. That survey aimed to find out what happened to patients with optic atrophy. Did they get well? Did they get worse? And was our treatment effective in controlling optic atrophy?

I am reminded in reading Duke-Elder tonight of the statistics in which he quotes me: "Of the untreated cases, 74 percent were blinded in a period of three years; all of them were blind in five years. Of those treated by the well-known methods of antiluetic treatment at the time, 24 percent of the optic-atrophy cases became blind in a period of five years, and all of them were blind in a period of eight years."

This was very damaging evidence, pointing out that the method of treatment at the time was not sufficient to control optic atrophy due to syphilis, to cure it, or even to arrest it. I had hoped that the essayists tonight would give us some information along those lines. Despite the fact that we preach early diagnosis of optic atrophy, it is true that our methods of treatment today are insufficient and inadequate. What suggestions do the essayists have in the way of modifying our methods of today to bring about a control of optic atrophy, or at least to reduce the incidence of blindness from this disease?

I wish to call your attention to an article published in Science of November 7, 1947, by Dr. Knisley of Chicago. In that article he speaks of blood sludging occurring in various diseases. He speaks of the red cells in the blood becoming sticky, and agglutinating in malaria and various inflammatory and infectious diseases. Dr. Knisley has probably opened up an entirely new field of pathology in the case of optic atrophy due to syphilis, namely the blood sludging occurring in the end arteries of the retina. Sludging means that the blood vessel caliber is

closed, the nutrition of the part ceases, and progressive optic atrophy develops. The question I wish to point out to the investigators tonight is this. Do we have anything to control optic atrophy even if it is diagnosed early? Are the methods used today —the use of penicillin, the use of heavy metals—sufficient to control optic atrophy, or are we going to lean upon Dr. Knisley for another suggestion so as to prevent blood sludging, and thereby prevent optic atrophy?

I wish to congratulate the authors of the article just presented, and I know they have some very valuable information for us in rebuttal.

Dr. Joseph V. Klauder (closing): One cannot answer Dr. Lehrfeld in an arbitrary manner, because there is so much variability in the course of syphilitic atrophy. We are all familiar with the rapidly progressive cases that pursue a downhill course regardless of treatment, and are blind in one year or less. In the slowly progressive cases, the prognosis is more favorable. If we exclude the rapidly progressive cases, we do not believe the inevitable result is blindness. We have a number of patients in the clinic whose optic atrophy has remained stationary for periods of observation ranging up to 18 years. We observed this in patients who had received different methods of treatment.

Certainly one is justified in being less pessimistic about prognosis than years ago; that era, for example, when the disease was treated with strychnine. There has been considerable addition to the therapeusis of the disease. Fever therapy, especially malaria, is to be stressed. The status of penicillin awaits evaluation.

Dr. George P. Meyer (closing): If you read the program, it says, "Syphilitic primary optic atrophy as a cause of blindness and importance of early diagnosis." I think we have shown tonight the importance of early diagnosis, because with a well-advanced optic atrophy the outlook is pretty poor. I remember when Dr. Lehrfeld's article came out in 1938 I felt depressed about it. I hap-

pened to have at that time a patient who had neurosyphilis and beginning optic atrophy, and I went to one of the local syphilologists in Jersey, and asked him to undertake the treatment of syphilis. He just shrugged his shoulders, and said, "Oh well they all go blind anyway," and he was associated with one of our larger teaching institutions in the city.

The patient was subsequently referred to Dr. Klauder, and he still has vision. Dr. Klauder did not have the pessimistic outlook as far as therapy was concerned. I think the first bright note was struck by the Baltimore investigators. I do not remember the figures exactly, but there is a direct ratio between the good prognosis and the amount of vision that was retained when a patient first reported for treatment. If a patient first reported for treatment industrially blind, the outlook was pretty poor. So it is you get figures like those of Dr. Lehrfeld and Duke-Elder who report that, within eight years, all patients become blind. That certainly is not the experience in our clinic for there are many patients who still have useful vision 8 or 10 years after the diagnosis of optic atrophy was made, and I think the first person to whom we have to point that lesson is the pessimistic ophthalmologist. Get him to feel that if he is alert enough to make an early diagnosis, very valuable vision may be saved for a patient.

M. Luther Kauffman,
Clerk.

CHICAGO OPHTHALMOLOGICAL SOCIETY

October 18, 1948

Dr. Arlington C. Krause, *president*

Clinical cases were presented by the Department of Ophthalmology, Veterans Administration Hospital, Hines, Illinois.

DISCIFORM DEGENERATION OF MACULA

R. D., a 29-year-old white man, entered

Hines Hospital on February 26, 1948, complaining of defective vision in both eyes for six months. He stated that on routine examination overseas in October, 1943, vision was: R.E., 20/40; L.E., 20/20. He had no complaint at that time. He received a medical discharge from the Army in 1943 because of rheumatic fever. In August, 1947, he was seen by an ophthalmologist who noted vision to be: R.E., 20/400; L.E., 20/70. He gave a past history of two attacks of bronchitis and one of probable rheumatoid arthritis.

When examined, his general physical condition was normal. Vision was: R.E., 20/300. Anterior segment, media, and lens were normal. Fundus showed a slightly elevated, sievelike, spongy gray mass, well circumscribed, oval in shape, occupying the macular area and containing red pinpoint spots; lateral to this was a small similar gray patch. Disc and vessels appeared normal.

Vision was: L.E., 20/30−2, correctible to 20/30+3. Anterior segment and media were normal. The lens showed a thin opacity of posterior lens capsule. The fundus revealed a mass in the macular area similar to that in the right eye, with a few small patches laterally. Within the large porous mass was a central red spot which suggested remaining normal macula.

Peripheral fields were normal; central field, right eye, showed a central scotoma surrounding the upper half of the fixation area for a distance of 5 degrees, including the fixation point. The left eye showed a pericentral doughnut-shaped scotoma circumscribing the fixation point and leaving 1 to 2 degrees free at the fixation point.

All laboratory tests revealed normal findings. A tentative diagnosis of disciform degeneration of the macula, bilateral, was made. Treatment consisted of nitrosclerin, vitamin-B complex, and thiamin.

The patient was discharged on March 19, 1948, but returned 10 days later because of sudden decrease in vision in the left eye. The lesion appeared to be the same as on previous admission except that the small area in the center of the macular area, which previously suggested normal retinal tissue, now appeared pale and degenerated. Vision was: L.E., 20/200.

Stereocampimeter showed definite central scotomas involving the fixation area bilaterally. He was given typhoid and nitrosclerin intravenously, as well as rutin and vitamin-B complex. Twenty-four days later the vision returned to 20/30+3, 5 point. He was discharged a few days later, and now returns with vision: R.E., 20/400; L.E., 20/300.

Final diagnosis: Disciform degeneration of the macula, bilateral.

DISCIFORM MACULAR DEGENERATION

J. E. A., a 32-year-old white man entered Hines Hospital on April 10, 1948, complaining of a small blind area in the right eye of two weeks' duration. The scotoma was located just below the fixation object and moved in the same direction as the eye. In 1943, he suffered loss of central vision in the left eye over a six months' period; there was no associated pain. He received a medical discharge in 1945. Past general history was negative except for an abscess in an upper incisor tooth.

General physical examination was normal except for an atrophic testis on the right side.

Examination of the eyes showed: R.E., vision 20/20, anterior segment, media, lens, normal; fundus showed a normal disc but the macular area appeared edematous and contained 4 or 5 hemorrhagic spots, mostly deep and round, and one superficial flame-shaped hemorrhage. A small dot of exudate was present.

L.E., vision, large objects only, not correctible; anterior segment, media, and lens normal.

The fundus revealed a normal disc, but temporal to the disc and overlying the macula was a white circumscribed elevated fibrous mass, about 3 disc diameters across. The

retinal vessels rose about 2 diopters to cross over it. The mass was fairly round but had a pseudopod in the upper aspect, and contained a slight amount of pigment. Temporal to the mass was a small circumscribed pigment patch. The retina was pale, suggesting change of a glial nature. The central field, right eye, showed a round scotoma about 10 degrees in diameter, situated just below the fixation point.

All laboratory tests and X-ray findings were within normal limits. Genito-urinary examination showed a mild chronic prostatitis, which improved under treatment. Dental examination revealed evidence of pyorrhea and three teeth were extracted.

The patient was put on rutin and thiamin therapy and one small injection of typhoid, intravenously.

Shortly after admission, more small hemorrhages together with waxy edema of the right macula became apparent. Vision decreased rapidly; on May 10th, it was 20/100 and the scotoma included the fixation point. There was a suggestion of a macular star. About 4 disc diameters from the disc at the 7-o'clock position was a small round gray exudate. Another oval gray patch of choroiditis was seen at the 1-o'clock position.

On May 17th, a small, round, blue exudate appeared 2 disc diameters from the disc at the 10-o'clock position. On May 18th, vision in the right eye improved to 20/70, and the scotoma appeared to be smaller. However, the vision continued to fall and by June 1st, it was 20/400; today it is 5/400, not correctible.

Final diagnosis: (1) Disciform degeneration of macula, bilateral, progressive on right, unchanged on left; (2) prostatitis, chronic, mild, improved.

IRIDOCYCLITIS, CHOROIDITIS, AND GLAUCOMA

S. G., a 34-year-old white man, entered Hines Hospital on March 19, 1948, complaining of progressive blurred vision and aching in the right eye of three days' duration, together with a feeling of "pressure," slight redness, but no discharge.

In January, 1943, he noted a spiderweb appearance over the right eye which lasted for three weeks. This recurred three months later and then cleared with vision of 20/20. The left eye was normal. He had a similar episode in 1944.

In January, 1946, he entered the hospital with the same complaints. At that time eye examination showed visual acuity: R.E., 20/100; not correctible; lids, sclera and lens were normal; 1+ mixed bulbar injection; iris muddy; pupil dilated to 5 mm. under atropine; slitlamp showed 2+ aqueous flare with many cells present, numerous keratic precipitates in delta configuration in lower third of cornea; the fundus revealed a faint red reflex but no details were visible.

The left eye was normal. A diagnosis of iritis, acute, recurrent, was made and he was discharged in six weeks. Vision: R.E., 20/20−3; L.E., 20/20. The family history was essentially negative. The patient had had usual childhood diseases and malaria in 1943, with eight recurrences.

General physical examination revealed some carious teeth and was otherwise negative. Examination of eyes: R.E., atropinized, vision was 20/40−1 with pinhole; lids normal; questionable pericorneal injection. The cornea showed some endothelial bedewing in lower inner quadrant. One minute pigment particle was noted on endothelium; 1+ aqueous flare, and few cells seen. The lens revealed a clump of pigment in lower half of anterior lens capsule. Vitreous floaters were present. The fundus showed a discrete circumscribed small bluish exudate, one disc diameter from the fovea. Tactile tension was normal. Left eye, vision 20/15, essentially normal.

All laboratory and X-ray tests, including smears for malaria, were negative.

Treatment was started with atropine solution and hot, wet dressings to the right eye, and a course of typhoid injections was given. Nose and throat and genito-urinary

consultation gave no significant findings. Brücellergin skin test, Volmer patch test, and first strength P.P.D. were negative. The vitreous floaters appeared to be decreasing on the 5th day of hospitalization, and vision was: R.E., 20/25; the peripheral field was slightly constricted, the central field normal. Second strength P.P.D. was positive, and old tuberculin was started.

On April, 18th, an increase in vitreous floaters was noted and the fundus was hazy. Old tuberculin was discontinued after five injections of 1:100 dilution in gradually increased doses. Vision was: R.E., 20/40 on May 1st, and decreased to 20/50—3 by May 3rd. The fundus appeared more cloudy.

One carious tooth was extracted and a slight ache developed in the right eye; the following day the tension rose to 65 mm. Hg (Schiøtz,); vision was 20/100. Retrobulbar injection and typhoid serum were given, with reduction of tension to 48 mm. Hg.

On May 11th, a paracentesis was performed. May 18th, the tension remained controlled; vision, 20/200; fundus, hazy and numerous keratic precipitates present.

On June 9th, the vessels in the fundus could be distinguished; a large yellowish-white exudate was seen in the superior nasal region, about 3 disc diameters across and about 5 disc diameters above the disc. This was suspected to be a tubercle.

On June 24th, the vision was 20/50 and the patient was dismissed for two weeks. On his return, vision was 20/30+2; tension, 26 mm. Hg (Schiøtz). The cornea was clear except for the paracentesis scar at the 7-o'clock position. The small discrete exudate area near the fovea was unchanged, as was the tubercle, and he was discharged.

Diagnoses: (1) Iridocyclitis, acute, recurrent, right eye; (2) choroiditis, acute, right eye, on tuberculous basis; (3) glaucoma, secondary to uveitis, right eye.

FAMILIAL CORNEAL DYSTROPHY

R. R. L., a man, aged 51 years, complained of progressive loss of vision since 1933; inability to wear glasses for more than a few minutes for near; intermittent redness of eyes and discharge in morning.

Eye examination was recommended when the patient was in third grade in school, but was not obtained. Repeated eye examinations since the age of 21 years revealed diminished vision. He was inducted into the Marine Corps, but not given target practice. He had had intermittent attacks of bilateral conjunctivitis, which improved with argyrol and warm boric-acid soaks. Corneal opacities were diagnosed in 1933 and glasses were prescribed, but the patient preferred 5- and 10-cent store reading glasses.

Family history revealed that his father died at the age of 61 years of a stroke. There was a history of special eye examinations. His mother died at the age of 67 years of diabetes. One eye had been enucleated; vision was poor with glasses. Four brothers had good vision. One brother had had one eye enucleated (traumatic). The other eye has "lattice-type dystrophy," and this man has been a patient of Dr. Fitzgerald. One sister has some eye trouble.

R. R. L. was first seen at Hines Hospital in 1931, at which time he was admitted for an injury. At that time vision was O.U., 20/50 correctible to 20/30. In 1933, the vision was unchanged, although the examiner described "fine stippling opacities of the cornea with clear centers seen bilaterally with slitlamp." In 1936 and 1946, vision had deteriorated to 20/100 and 20/200 respectively. At present:

	Searchingly	P.H.	Mydriatic
O.D.	20/50	20/50	20/70
O.S.	20/30	20/30	20/70

Own Glasses

2.5D sph., 20/60
4.0D. sph. ⊂ 2.0D. cyl. ax. 180°, 20/30

Examination of both eyes showed tactile tension to be soft; pupils equal and reacted to light, directly and consensually, and to accommodation; moderate chronic injection

of palpebral conjunctiva; marked anesthesia of corneas, which grossly had appearance of glass eyes badly scratched through the central areas; lens, media, fundus, negative.

Slitlamp examinations showed both corneas to have multiple discrete and confluent gray-white lesions of varying size and shape through all layers, confined to the central 6 mm.; pupil zones relatively clearer, with fewer lesions. The lesions themselves appeared like clumpings of a snowflakelike substance, in solid nodes and complete and incomplete doughnutlike rings. The overlying epithelium was irregular and the majority of the lesions were in the superficial stroma. The periphery was not entirely clear but had what appeared to be a gerontoxin in the inferior one half.

Discussion. Dr. James E. Lebensohn said that all these patients show the juvenile type of disciform degeneration of the macula. Three very similar cases were illustrated by Adler, in 1944, and, although the senile form of disciform degeneration of the macula is more commonly seen, the first cases reported were also of the juvenile type. The abiotrophies are generally not restricted to one age level. Amaurotic family idiocy has both infantile and juvenile types. Hereditary macular degeneration can be classified by age incidence into 4 of 5 groups. There is as yet no treatment for the condition. Although temporary remissions may occur, the inevitable end is poor central vision.

Dr. Charles A. Bahn (New Orleans) felt that these cases represent the ophthalmic condition we are most frequently called upon to diagnose and treat—atypical senility. Unfortunately, few people are like the one-horse shay of Oliver Wendell Holmes; some of the billions of cells which constitute the body are dying and being reborn every minute. The constitutional death and replacement rate varies widely in different tissues in different persons, and at different periods of life. In the retinal neuro-epithelium, for example, there is practically no replacement after birth. Hence, if these cells

have a constitutional predisposition to senility, function becomes permanently lost before death. If this process takes place in childhood, it is called Best's disease; in adolescence, Stargard's disease; and in middle life, Behr's disease. These are essentially the same condition, varying only at the time at which presenility actually manifests itself. The macula is usually first involved because it is phylogenically the oldest part of the retina and more highly specialized. The absence of repair is illustrated in the lack of new blood-vessel formation.

The younger ophthalmologists especially would do well to obtain a better understanding of the structural and functional evidences of normal and abnormal senility in all parts of the eye because of their diagnostic importance.

Dr. Homer Field said that the third case demonstrates the fact that, when there is posterior uveitis and glaucoma, it is hard to see what is left of the fundus. Solitary tubercles of the fundus and choroid are not too rare, neither are they common. Usually they occur in the choroid in the region of the posterior pole, or at the equator, and may be quite elevated, or under the layers of the retina and fairly flat. Sooner or later detachment occurs, which may be prominent or fairly flat. The tubercle tends to show a considerable amount of pigment. In this case, the fact that there was little disturbance of pigment is noteworthy, and it is a question whether this is a solitary tubercle or a case of posterior uveitis on a possible tuberculous basis.

The relationship between extraction of the tooth in this case and exacerbation of the condition of the eye is interesting. It demonstrates that, in differential diagnosis, one must not lose sight of more rare conditions such as Boeck-Schauman's disease which can cause considerable posterior involvement of the eye and yet does not produce too much acute inflammation. Toxoplasmosis must also be considered. In the absence of other positive findings, this could well be a solitary

tuberculous lesion; however, there are evidences of older, smaller lesions, which may or may not have been the same type. It is always interesting to think in terms of miliary tuberculosis when a solitary tubercle is found. The general condition of this patient does not speak for any great amount of tuberculous involvement.

Dr. Cyril Crane said that the fourth case was selected because it was felt that it represents a classical clinical picture of familial corneal dystrophy, first described by Grünow in 1890. It is obvious that there are many similar disease processes described under various names which are essentially the same clinical entity, probably with minor differences in morphologic detail.

Familial corneal dystrophy is an hereditary degenerative process occurring usually bilaterally, the symptoms first becoming manifest at about the age of puberty with insidious loss of vision; it is characterized by deposition of hyalinlike material in the layers of the substantia propria of the cornea, particularly the central portion thereof.

The first type described in the literature by Grünow was of this type; he later elaborated on the description by giving the histologic findings, in 1898, and, about 1917, was able to report on transmission of the disease through three generations; in 1933, he reported on four generations, all the cases having been examined by him personally.

This patient, so far as can be determined from the history, had some difficulty even prior to the age of puberty. Several cases have been reported in which it was thought that, biomicroscopically, the findings could be detected before the age of puberty. Obviously the loss of visual acuity here was so insidious that little attention was paid to it until about 1931. However, the patient was obviously otherwise physically well qualified, inasmuch as he was selected for the Marines in World War I; the qualifications for that service have always been high. He was never at any time put on the rifle range, which is an important part of the Marine Corps, so

it must be assumed that at that time, when he was 19 years old, there must have been considerable loss of visual acuity.

Thirteen years later, when seen at Hines Hospital, in 1931, he showed the early slit-lamp findings of pearly white dotlike lesions occupying principally the anterior third of the substantia propria in the central area. At the present time, at the age of 51 years, the patient's visual acuity has been markedly reduced and he now has variable types of lesions in all layers of the substantia propria, some of which could be described as of the reticular variety. However, the lesions predominantly are nodular as described by Grünow, varying in size and shape, many with a rather characteristic doughnut or ringlike appearance and, for the most part, in the peripupillary zone, which is also rather characteristic.

Dr. J. Robert Fitzgerald mentioned that the younger brother of the fourth patient reported had lost one eye due to trauma many years ago. The corneal changes started some time during adult life and there was a corneal stippling similar to that seen in the older brother. The opacities were primarily in the axial portion of the cornea with a perfectly clear periphery. When last seen, about a year ago, the lesions were comet-shaped and clublike, alphabetical, and interlacing, with a rather lattice-shaped pattern in the central portion of the cornea. The opacities were much more prominent, although the visual level was apparently about the same as that of his brother. The opacities were of such density that they could be seen at 4 or 5 feet with ordinary room illumination; whereas, in this patient, they were visible primarily with retro-illumination.

NEUROFIBROMATOSIS OF THE EYELID

Dr. Max M. Kulvin spoke on the surgical repair of neurofibromatosis of the eyelid and reported on two cases. His paper is published in full on page 1231 of this Journal.

Discussion. Dr. James E. Lebensohn said

that, at first glance, one is discouraged from working on these cases because everything seems so disorganized. However, although the final result leaves much to be desired, it is, nevertheless, better than either the surgeon or the patient anticipated. All the patients were well satisfied with the results.

Dr. Homer G. Field stressed the use of the sliding flap with the tarsal plate in reconstruction of the eyelids. In these two cases there was marked destruction of the eyelid and, in one, there was absolutely no tarsus left—the conjunctival surface was completely obliterated. It is simple to make a tarsal conjunctival flap and slide it into position in the upper lid. The technique was designed originally by John Wheeler and later modified considerably by Wendell Hughes.

In this case the technique was actually a Wheeler-Hughes operation in reverse; instead of bringing the upper tarsal plate down to the lower lid, the lower tarsal plate was brought to the upper lid.

For overcoming ptosis any suspension procedure may be used, as a fascia lata suspension from the superior rectus; where there is so much redundant tissue, however, suspension from the brow margin is probably a better procedure.

Reconstruction of an eyelid is sometimes a problem. Where there is a large tumor mass, with complete destruction of the functioning portion of the lid, it is difficult to preserve or restore function. If ptosis is permitted to remain complete, a functioning result is not obtained.

Dr. Max M. Kulvin (closing) said that in one case the final result so far as vision is concerned is poor. Some complication developed which caused corneal scarring and not much vision was obtained, but the patient had had none for so long that he was not concerned about that.

SURGERY OF ORBITAL IMPLANTS

DR. NORMAN CUTLER (Wilmington, Delaware) discussed the ideal implant which should accomplish certain objectives

such as permanence, motility, and a good cosmetic result. The integrated type implant is being improved in every respect until it now merits serious consideration by all ophthalmic surgeons. The only factor still to be determined is the one of permanence. This, of necessity, will require more than the few years so far available. The cosmetic result and motility are uniformly good. The operation has been simplified and shortened and the possibility of postoperative complications has been greatly reduced or eliminated. Although the present advances are due to the discovery and use of the plastic artificial eye, this material is still not ideal from the aspect of minimal tissue reaction.

The subject was discussed under the general headings of: (1) Types of implants—their advantages and disadvantages; (2) evisceration versus enucleation, with indications for each; (3) illustrations of operative procedures; (4) possible complications; (5) possibilities in reimplantation procedures; (6) a general discussion of statistics.

It is believed that statistics can be overemphasized in either advocating or condemning any procedure. They may be particularly misleading when constant experiment and development of a procedure is taking place and when these procedures must, in the nature of things, be carried out on human subjects.

Discussion. Dr. V. M. Leech asked whether Dr. Cutler had discarded ring implants in favor of those that have tantalum mesh only. Also, some surgeons used charred bone balls instead of glass and other smooth materials, and he wondered whether Dr. Cutler had had any experience in removing such implants in order to insert the more modern ones of which he spoke.

Dr. Cyril V. Crane asked how selection is made for reimplantation in the absence of previous history or record as to the original operative procedure, and what criteria are used to determine the presence of adequate healthy conjunctiva for reimplantation.

Dr. J. Robert Fitzgerald asked whether

Dr. Cutler had any operative technique that he feels may prevent granulomatous changes around the neck of the implant. Many times there is bleeding for a considerable period after the prosthesis has been implanted.

Dr. Norman Cutler (in closing) said that the ball and the ring implant is not being used. In his opinion, over a period of years tissue which has formed around a ring will gradually erode through. A number of his cases had been under observation for more than three years, but he felt there is a tendency, as the tissue stretches over a hard surface, for it to gradually wear thin. The principal advantage of the ring implant is that it is a space-developing implant when it turns;

however, because of the difficulty of insertion it will probably not be used. He had not removed any bone balls to put in implants. One would probably have to cut the tissue off with a knife.

When a reimplant is put in, more conjunctiva is available in the fornix. The only criterion is movement in the stump. If there is no movement, there will be no improvement. Most do have quite adequate movement, but some do not.

The problem of granulomatous tissue cannot be answered as yet. He had cauterized it on occasion, but had felt that if it did occur it would not be a permanent problem.

Richard C. Gamble,
Secretary.

OPHTHALMIC MINIATURE

I have lately seen two cases in which there was a paralysis of all the parts supplied by the nerves of the third pair, viz. three of the recti muscles, one of the obliqui, and the levator palpebrae superioris, so that the upper eye-lid could not be elevated, and the globe was drawn outwards by the external straight muscle. In both instances the pupil was largely dilated. It may, perhaps, be suspected that the optic nerve was insensible; but this was not the case, for when the patient looked through a minute opening in a card, producing what may be called an artificial contracted pupil, vision was perfect. I mention these facts, because they may assist in the investigation of the subject, for further inquiry is undoubtedly necessary. If a perfect state of motion can subsist in the iris when the retina is perfectly insensible, the changes in the pupil cannot be referred to the effect of light upon the optic nerve. To what, then, it may be asked, are we to refer them? How are they to be explained? I confess that I cannot explain them.

Sir William Lawrence, *A Treatise on the Diseases of the Eye*, 1833.

AMERICAN JOURNAL OF OPHTHALMOLOGY

Published Monthly by the Ophthalmic Publishing Company

RECENT TRACHOMA STUDIES

In reviewing wartime trachoma studies for the two volumes of *Ophthalmology in the War Years*, edited by Dr. Meyer Wiener, I was impressed by the dearth of significant reports on the disease still considered by many to be the eye disease of greatest worldwide importance. Since the war, however, a number of significant studies have appeared, notably by Professor Mitsui and his collaborators in Japan and by Professor Bietti and his collaborators in Italy.

The Japanese studies were actually reported during wartime but only became available to English readers in 1948. They are summarized in an article by Professor Mitsui in this issue of the JOURNAL.

These investigators confirmed anew that human volunteers could be inoculated with trachoma. In their experience the average incubation period was from 5 to 6 days. The onset was always acute and Prowazek-Halberstaedter inclusion bodies were always present, in numbers proportionate to the severity of the clinical signs.

The question of the frequency of inclusion bodies in the chronic stage of the disease was reexamined. Typical inclusions were

found in 537, or 65 percent, of 823 chronic cases and in 85 percent of 392 cases with typical clinical symptoms. Tissue sections were positive for inclusions in 108, or 92 percent of 117 cases. Inclusions were demonstrated in the epithelium of the lacrimal sacs of 5 of 6 patients with early conjunctival trachoma and were noted in the canaliculi of 2 additional cases. ·

The inclusions were never found in the subepithelial tissues and the absence of trachoma virus in these tissues was proven in 10 cases of typical trachoma: subepithelial tissue, obtained in all 10 cases without penetration of the conjunctiva, was shown to be noninfective for human volunteers;· control inoculations with conjunctival tissue from the same cases resulted in typical infection. Furthermore, subconjunctival inoculation of volunteers with infective material failed to induce trachoma; whereas, a control inoculation of the conjunctiva with the same material resulted in typical experimental trachoma.

In tissue-culture experiments, the Japanese investigators were unable to obtain growth of the virus in serial cultures, although the first two cultures of trachomatous epithelium were infective. On the basis of inoculation experiments on blind infant eyes, they claim to have established an identity between inclusion blennorrhea and trachoma but their evidence on this point is inconclusive. Interestingly enough, they were able to infect the human cervix with trachomatous materials, a finding comparable to that of Braley who obtained infection of the cervix of the female baboon with trachoma virus.

The experiments of Bietti and his collaborators dealt primarily with the therapy of trachoma, although Bietti covered all aspects of the disease in a monograph entitled "Il Trachoma," published in Rome in December, 1947. In a resume of his studies on the sulfonamide and penicillin therapy of trachoma (Revue Internationale du Trachoma, 25: 115, 1948), Bietti concluded that all the ordinary sulfonamides were active against

trachoma but that he preferred paraminophenylsulfamide.

He recommended an oral dosage of 2.5 gm. daily for 10 days or longer; topical applications he found less valuable. The drug was most effective against the secreting forms of the disease and against pannus and corneal ulceration. He found that 50 percent of all cases were cured completely and that about 10 percent of the actively secreting forms and 40 percent of the chronic hyperplastic forms were resistant.

He stated that recurrences were frequent after short treatment periods and that reinfections occurred in about 5 percent of cases. He noted that about 10 percent of subjects had an intolerance to the sulfonamides but that vitamins C and B complex were useful in reducing the intolerance. He was able to show that patients on sulfonamide therapy were noninfective for monkeys and man.

Professor Bietti found that penicillin had some curative effect on trachoma but that it was less effective than the sulfonamides. He noted the disappearance of epithelial inclusions within 72 hours. The effect of penicillin on secondary infection was marked. Streptomycin also had a marked effect on secondary infection but little if any on trachoma virus itself. Tyrothricin was of no value.

Of special interest is an article by Bietti and Pasca (Boll. Soc. ital. biol. Sper., 24:82, 1948) reporting the inefficacy in trachoma of paraminobenzoic acid, a substance which is highly reactive against the Rickettsiae. The investigators concluded that this lack of sensitivity of trachoma virus to paraminobenzoic acid, combined with its sensitivity to the sulfonamides and penicillin and its negative Weil-Felix reaction, ruled out the existence of any close relationship between trachoma virus and the Rickettsiae.

These etiologic and therapeutic studies constitute important contributions to our knowledge of this still most destructive of eye infections.

Phillips Thygeson.

CORRESPONDENCE

Editor,

American Journal of Ophthalmology:

I should like to bring to your attention that the 1949 *Transactions* of the American Ophthalmological Society, published in book form, may be purchased by advance subscription.

This volume, priced at $12.00, contains the scientific papers presented at the annual meeting and the theses for membership. It may be ordered from the Editor:

Dr. Wilfred E. Fry
1930 Chestnut Street
Philadelphia 3, Pennsylvania

All orders must be received by December 1, 1949.

(Signed) Maynard C. Wheeler,
New York, New York.

PUPILLARY DILATATION BY

DATURA STRAMONIUM

Editor,

American Journal of Ophthalmology:

In the March, 1949, issue of the JOURNAL, Dr. Lucian Bauman published an interesting article on "Accidental cycloplegia by Jimson weed," in which he stated that "there are only 7 reported cases of accidental cycloplegia (by Datura stramonium) in the world literature during the past 50 years; 3 in the United States, 1 in Cuba, 1 in France, and 2 in French Morocco," and lists the references.

My name is omitted, although I observed a case of accidental pupillary dilatation due to Datura stramonium and reported it in the *Santa Fe Medical Review* (Argentine Republic) in the issue for October-December, 1940, on pages 26 and 27. In this case, accidental cycloplegia occurred while the patient was washing her hair with an infusion of leaves of the Datura stramonium and un-

thinkingly let some of the liquid run into her eyes. Experimentally, I have produced maximum mydriasis in eyes into which I instilled a filtered infusion of leaves of this plant.

In effect, the above paragraph is what I published in the *Santa Fe Medical Review,* and I believe that this summarized reminder is of interest as a marginal note to the recent work of Dr. Bauman.

I should like to avail myself of this opportunity to advocate the exchange of medical reviews with their articles summed up in several languages so that oculists of each country can know what is published abroad.

Santa Fé, República Argentina.

USE OF WATER BATHS TO PROMOTE
WOUND HEALING

Editor,

American Journal of Ophthalmology:

I have found the following procedure for the management of ocular wounds to be most successful and to fulfill these aims: (1) early closure of the wound, (2) diminution of the scar, and (3) retention of the greatest amount of visual function.

After all visible debris has been removed, the wound is submerged in a water bath as warm as the patient can stand for three quarters of an hour, warm water being added to the bath from time to time to keep the temperature even. The patient is instructed to rotate his eye and to blink occasionally.

Following local anesthesia with novocain and adrenalin, a careful wound toilet is made. It is surprising how many foreign bodies not visible before the bath are visible after it. No tissue is trimmed for the parts not possessing vitality will be eliminated. Do not scrub or scrape the wound surface. If necessary, use sutures but do not complete the sewing for the sutures are to be used to guide the healing. Wound closure is attained by submerging the wound daily in a water bath. After the toilet is completed, the

wound is bandaged. The bandage is changed daily at which time the water bath is repeated.

As soon as possible after healing starts, remove the sutures and increase the number of water baths to 3 or 4 daily. As the scar contracts, the continued water baths bring hitherto invisible foreign bodies to the surface. It is surprising how quickly old and recalcitrant wounds respond to this treatment, bringing to mind the old Latin proverb: "Medicus curat, natura sanat."

Although I claim nothing new in this procedure for wound management, I believe it is well to point out that the fear of washing a fresh wound with water has no basis in fact. Bathing infected as well as sterile wounds in warm water once or more times daily for 30 to 45 minutes not only promotes healing but produces a more satisfactory closure.

In my opinion, the best first aid in an ophthalmic emergency is to submerge the wound in warm water. The wound bath is followed by careful dressing, the use of a sulfonamide powder, or penicillin, and bandaging. Secondary sutures are used only if necessary.

BOOK REVIEWS

ELEMENTS OF GONIOSCOPY. By Archimede Busacca. São Paulo, Brazil, Rossolillo, 1945. 187 pages, 106 illustrations, 1 color plate, bibliography, and index. Price, not listed.

The appearance of this splendid textbook of gonioscopy has not hitherto been reviewed in these pages. It is worthy of special note for its author has contributed much original thought and information to the subject and was the first to bring together in book form the rich material on gonioscopy in the literature and from his own experience.

The book is written in French, but it is so well illustrated that it is not difficult to follow. After discussing at considerable length the technique of gonioscopy (Goldmann's contact lens and biomicroscopy), the anatomy of the iris angle and its appearance in gonioscopy, the author proceeds, in Part II, to describe the pathologic conditions of the angle as studied in gonioscopy. These conditions include anterior synechias, uveitis, after operations, in injuries, keratitis, adherent leukomas, dislocated lens, iris coloboma, glaucoma capsularis, and other forms of glaucoma.

Part III discusses experimental gonioscopy in iridectomized eyes under the effect of eserine or atropine. Eserine makes the ciliary bodies visible by traction; whereas, atropine retracts them.

The growing number of books on gonioscopy in English and French signifies the extent of its importance and interest to ophthalmologists. No representative ophthalmic library should pass up this excellent modern contribution to our science.

Derrick Vail.

LA GONIOSCOPIE. By Jules François. Louvain, R. Fonteyn, 1949. 220 pages, 156 illustrations of which 48 are in color, bibliography. Price, not listed.

This beautifully written, printed, and illustrated monograph represents the results of many years of study by the author. It is the second of its kind to appear in the French language, and was prepared at the request of the Belgian Society of Ophthalmology. It forms a welcome addition to the previously published volumes on the subject, notably those of Uribe Troncoso and Archimede Busacca.

The various chapters deal with the anatomy of the iris angle, the physiologic importance of the canal of Schlemm, the technique of gonioscopy, the normal gonioscopic aspect, congenital anomalies, ocular injuries, tumors, anterior synechias, uveitis, primary and secondary glaucoma, and postoperative gonioscopy.

Dr. François has arranged his material very well and the illustrations are eminently satisfactory, so that even the non-French-reading ophthalmologist will gain much important information just by leafing through the book. Those who read French will enjoy the fluent and lucid style of its author.

Derrick Vail.

TRANSACTIONS OF THE OPHTHALMOLOGICAL SOCIETY OF AUSTRALIA. Volume 7, 1947.

The president's address, by Darcy A. William, is an interesting history of ophthalmology in Australia. The medical journals are important repositories of the data on which the story is based and their histories are included in the address. The *Australian Medical Journal*, the earlier of the two major roots of the present *Medical Journal of Australia*, which is one of the best of the world's weekly journals of general medicine, was founded in 1856.

H. M. Macindoe, in an essay on "Research organization and training overseas," recounts his experiences on an extensive visit to the medical centers of Europe and America.

J. Bruce Hamilton's "Further contribution to the study of dry eyes" amplifies his earlier study of keratitis sicca, Sjøgren's syndrome, and some unclassified cases. He clarifies the relations of these diseases to desiccation keratitis, mustard-gas keratitis, Plummer-Vinson syndrome, Mikulicz's disease, and iodide "mumps." He presents a follow-up study of the patients reported in 1940 and adds a further 24 cases of dry eyes.

Tostevin gives an adequate discussion of eye protection in industry and there are numerous short reports, 1 to 5 pages in length, on 15 other topics.

F. H. Haessler.

ARCHIVOS Y MEMORIAS DE LA SOCIEDAD DE OFTALMOLOGÍA DEL LITORAL (Organo oficial de la Sociedad de Oftalmología del Litoral). Rosario, Argentina, Volume 1, 1947-1948. Paper covers, 272 pages, illustrated.

The title of this volume, and of the society which it represents, furnishes a good example of linguistic idiom. Literally, or in the dictionary sense, we are dealing with the proceedings of the ophthalmological society of the coast (of Argentina). However, the actual broader significance appears to be "Ophthalmological Society of the Provinces (or outlying areas) of Argentina, the term "litoral" or "coast" being used in this greatly broadened sense.

The society's center of action is the great city of Rosario, the second largest city of the South-American republic, with a present population well over half a million, located 200 miles northwest of Buenos Aires, on the huge river Paraná, which rises not very far from Rio de Janeiro and runs 2,720 miles before reaching the sea at the estuary called La Plata.

The very progressive city of Rosario, with an important university and medical school, gave birth in 1938 to the vigorous second ophthalmological society of Argentina. That society, just now under the presidency of Enrique V. Bertotto, the vice-presidency of Arturo Reca, and the secretaryship of Juan Vila Ortiz, has already attained a membership of 67 coming from widely separated cities of the country. It has welcomed a number of foreign ophthalmologists at its periodical meetings, including two from the United States.

The present volume, the first annual volume of transactions published independently by the society, includes about 30 papers. Perhaps the most ambitious theme presented is the very painstaking effort of Bertotto to develop a machine for making mathematically photographic tracings of the anterior segment of the eye upon which to base a mold of the anterior segment in producing a contact lens. This technique he calls stereophotogrammetry.

W. H. Crisp.

ABSTRACT DEPARTMENT

Abstracts are classified under the divisions listed below. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

1. Anatomy, embryology, and comparative ophthalmology
2. General pathology, bacteriology, immunology
3. Vegetative physiology, biochemistry, pharmacology, toxicology
4. Physiologic optics, refraction, color vision
5. Diagnosis and therapy
6. Ocular motility
7. Conjunctiva, cornea, sclera

ANATOMY, EMBRYOLOGY, AND COMPARATIVE OPHTHALMOLOGY

Aurell, G., and Kornerup, T. **The glandular structures at the corneoscleral junction in man and swine; the so-called "Manz glands."** Acta ophth. 27:19-45, 1949.

The object of this investigation was to clarify the conflicting data on the presence and nature of the glands described first by Manz in 1859. The material for the study consisted of a large number of specimens of the limbal conjunctiva of adult and new-born swine and man, and human embryos of different ages; most of the specimens were stained in toto. As the photomicrographs show, the structures described as the glands of Manz are only solid epithelial buds or tubules, which are rudiments of the lacrimal glands present in the embryonic limbal conjunctiva of swine. Balls of epithelium in the limbal conjunctiva of swine have no secretory function. In man there are no glands of Manz nor lacrimal glands at the limbus during any period of development. The corneal epithelium at the limbus grows into the conjunctiva as thick, often branching ridges; parts of these sometimes become isolated and form solitary epithelial balls, which may simulate glands, but which are not glands histologically, and have no secretory function. They may possibly give rise to conjunctival cysts. (17 photomicrographs.)

Fornes Peris, E. **The corneal innervation. Clinical considerations.** Arch. Soc. oftal. hispano-am. 9:237-244, March, 1949.

The author demonstrates with photomicrographs that the classical conception of intraepithelial corneal innervation is erroneous. There is no nerve plexus in the epithelial corneal layers, and innervation stops in the basal membrane. The patient is often unconscious of a foreign body on the cornea until the subepithelial nerves become irritated; even then he notes discomfort and lacrimation but is frequently not conscious of the foreign body, and may not seek ophthalmologic help for several days. The relief of pain when a corneal erosion is epithelialized is further clinical proof. (4 photomicrographs.)

Kokott, W. Functional anatomy of the choroidal membrane. Arch. f. Ophth. 148: 706-724, 1948.

The author studies isolated choroids of human eyes. To present their elastic framework some were digested with 4 percent potassium hydroxide. Further information was obtained by studying the directions along which the choroidal tissue splits most easily. It was found that the choroid and ciliary muscle represent an anatomic entity. The ciliary muscle serves as the tensor choroideae and helps to fill and empty the blood vessels of this membrane. Because of ganglionic cells in the choroid this mechanism, which controls the blood supply of the eye and the intraocular pressure, is to some extent autonomous. Ernst Schmerl.

Lopez Enriquez, M. The presence of medullary fibers in the retina. Arch. Soc. oftal. hispano-am. 9:367-389, April, 1949.

The author describes a patient with bilateral symmetrical medullated retinal fibers. The blind spot was somewhat enlarged and dark adaptation was retarded. The author critically reviews the literature on the disappearance of myelinated nerve fibers and emphasizes that their degeneration is of the descending type. A modification of Golgi-Rio-Hortega method of staining nerve tissue is described, and the course of the oligodendrial fibers described and illustrated. It is believed, on the basis of their anatomic course, that the oligodendrial fibers of the optic nerve are myelogenic, and the myelinated fibers of the retina are the result of a congenital anomalous extension of oligodendrial fibers into the retina. (11 figures.)

Trantas, N. G. Biomicroscopy of the zonule in normal eyes. Biomicroscopy of the ciliary body in two cases of surgical aphakia. Arch. d'opht. 9:31-38, 1949.

Trantas reports on the biomicroscopic examination of the zonule in normal eyes after full dilatation of the pupil by subconjunctival injection of 1-1000 adrenalin solution and with the Koeppe-contact glass. The zonule is examined both by direct and by retro-illumination, and detailed descriptions are given of the hyaloid membrane, the posterior fibers of the zonule, and the space between the hyaloid membrane and the posterior zonule. Trantas notes that the zonules at the equator are visible, as well as some of the most anterior ones. The triangular space (canal of Hannover) between the anterior and posterior zonule fibers is often sharply defined although traversed by a variable number of fibers from the equator of the lens. The author describes the complete illumination of the zonule by retroillumination and the visualization of the ciliary processes across the iridocrystallin space. He notes the differences in the appearance of the zonule and hyaloid membrane in myopia, in iritis, and in minimal subluxation of the lens, and stresses the clinical value of these observations.

Trantas reports two cases of surgical aphakia in which he was able to examine completely the ciliary body. He used a special flat-surface contact glass. The findings in the two cases are described in detail. The fundus of the normal eye can easily be visualized biomicroscopically up to the ora serrata and, with more difficulty, anteriorly. Phillips Thygeson.

GENERAL PATHOLOGY, BACTERIOLOGY, IMMUNOLOGY

Braley, A. E. Experimental studies of inclusion blennorrhea: isolation of a virus. Arch. Ophth. 41:151-171, Feb., 1949.

The virus of inclusion blennorrhea is similar to that of trachoma, lymphogranuloma venereum and psittacosis. Attempts were made to grow the virus of

inclusion blennorrhea by direct inoculation of chorioallantoic membrane, direct inoculation of yolk sac and in fluid tissue culture, all without success. Repeated blind passages through mice were carried out with the isolation of a virus which was considered as possibly the agent of inclusion blennorrhea. Mouse brain material containing this isolated agent produced a conjunctivitis in the baboon. The inclusion bodies could not, however, be recovered from the conjunctival scrapings of the baboon. Baboon eyes that had been inoculated with mouse brain material were immune to the inoculation with inclusion body scrapings. The agent from mouse brain grew well in the developing hen's eggs and could be transferred from the eggs back into the mice without difficulty. Detailed filtration, staining and neutralization tests were carried out. From these studies it was concluded that a new, unknown virus had been isolated; however, this new virus may represent a variant of the virus of inclusion blennorrhea.   John C. Long.

Campbell, F. W., and Michaelson, I. C. **Blood-vessel formation in the cornea.** Brit. J. Ophth. 33:248-255, April, 1949.

In a series of experiments it was determined that corneal lesions beyond a certain critical distance from the limbus produced no vascular response. At less than this distance a vascular area resulted which was in the form of an isosceles triangle. The vascular responses were quite constant in size with similar lesions, which suggest that a stimulating factor is released from the lesion. (4 photomicrographs.)   Orwyn H. Ellis.

Foss, Bjørn. **Experimental anaphylactic iridocyclitis.** Acta path. et microbiol. Scandinav. suppl. 81:1-127, 1949.

This study was undertaken to understand the unusual behavior of a patient with Behcet's syndrome characterized by extensive atrophy of the iris, retinal hemorrhage, ascending atrophy of the optic nerve, and relapsing hypopyon uveitis. The oral mucosa showed aphthous efflorescences and on the genitalia numerous superficial ulcers and blisters were seen. Cutaneous tests with tuberculin, trichophytin, staphylococcal vaccine, and omnadin showed a general hypersensitiveness. He was especially sensitive to staphylococcus vaccine. Intradermal injection of 1/1000 cc. of the usual staphylococcal vaccine caused a huge infiltration, sometimes with abscess formation, and always was followed by an attack of hypopyon uveitis in one to three days. Each injection was also followed by necrotic infiltration at the site of previous ones. After a series of blood transfusions the patient was free from attacks.

When 0.1 cc. of foreign serum or egg albumin is injected into the vitreous of healthy albinotic rabbits an iridocyclitis will appear after a constant incubation period. This reactive iridocyclitis is of an anaphylactic nature. Antigen is still present after the constant incubation period, and this antigen will unite with the specific antibodies of the uveal cells. This reaction is called primary anaphylactic iridocyclitis. Rabbits that have had primary anaphylactic iridocyclitis will react with a new iridocyclitis to intravenous or subcutaneous injection of a homologous antigen. Occasionally the iridocyclitis is bilateral. This iridocyclitis is designated as secondary anaphylactic iridocyclitis. It will develop within a few hours after an intravenous injection and within 24 hours after a subcutaneous injection, but no iridocyclitis will develop after an intracutaneous injection because the antigen is fixed to the cells and does not enter the circulation.

Animals that have received a general sensitization will develop a reactive iridocyclitis as an immediate result of intravenous injection of homologous antigen,

provided that the sensitization had occurred at least eight days before.

Rabbits that have had primary anaphylactic iridocyclitis of one eye will respond with a bilateral iridocyclitis 24 hours after an injection of the homologous serum into the other eye. This reaction is called sympathetic anaphylactic iridocyclitis; it does not correspond to the clinical form of sympathetic ophthalmitis.

Precipitation tests showed that the formation of antibodies following injection of 0.1 cc. of horse serum or egg albumin into the vitreous was considerably more marked than when the same amount of antigen was injected intracutaneously. The cutaneous reactions, too, revealed that intraocular injection of the same amount of antigen sensitizes the animal to a greater degree than cutaneous or intravenous injections. After primary anaphylactic iridocyclitis animals constantly develop local anaphylactic reactions as a result of intracutaneous injection. Even the 1 to 1000 antigen dilution caused a large infiltration with a central area of hemorrhages and necroses. The subcutaneous tissue, too, presented hemorrhages and dilated, blood filled vessels.

Scuderi, Giuseppe. **More about hemorrhagic allergy and the eye (experimental attempts to inhibit the Sanarelli-Schwartzman phenomenon).** Ann. di ottal. e clin. ocul. 74:512-522, Sept., 1948.

The Sanarelli-Schwartzman phenomenon is a necrotico-hemorrhagic reaction occurring when a bacterial filtrate is injected intravenously in a previously sensitized animal. Experimenting with rabbits, Scuderi found that the phenomenon could be inhibited by artificially induced fever but not by injections of antistin (a synthetic antihistamine compound). The antiallergic effect of pyrexia cannot be due to an antihistaminic action, and histamine is not a determining factor in the production of the Sanarelli-Schwartzman phenomenon. (References.)

VEGETATIVE PHYSIOLOGY, BIO-
CHEMISTRY, PHARMACOLOGY,
TOXICOLOGY

Bonavolontá, G., and de Bernardis, E. **Effects of Filatov's tissue therapy on experimental retinal pigment degeneration in the rabbit.** Bol. d'ocul. 28:65-76, Feb., 1949.

Retinal pigment degeneration was produced in rabbits by intravenous injections of one cc. of 4.5-percent solution of sodium iodide per kilogram of body weight. Tissue therapy consisted of implantation of placenta according to the Filatov method and injections of palcental extracts and of

cod liver oil. The development of experimental retinal degeneration was inhibited in animals treated with both cod liver oil and placenta transplantation. Histologic examination confirmed the clinical observation. Controls treated with organ lysates of liver and of embryonic tissue did not respond with inhibition of the degenerative process in the retina. The mode of action of the effective materials is discussed. (References.)

K. W. Ascher.

Cibis, P., and Hochgeschurz, G. **Pressure experiments dealing with the effects of ischemia upon the retinal function.** Arch. f. Ophth. 148:752-760, 1948.

The authors used H. K. Mueller's dynamometer to produce increased intraocular pressure in man and studied visual acuity and visual fields in relation to the diastolic and systolic bloodpressure. They conclude that the diminished efficiency of the eye in diseases which have increased tension is caused by circulatory disturbances, not by primary changes of the optic nerve. Ernst Schmerl.

Cruthirds, A. E. **Sulfur metabolism and its relation to wound healing in ophthalmology and otolaryngology.** Tr. Am. Acad. Ophth. pp. 596-604, May-June, 1949.

In the treatment of many types of acid and alkaline burns of the eyes a 5-percent solution of hydrosulfosol in castor oil is recommended. Hydrosulfosol is a sulfadryl preparation and acts as a reducing agent. Sulphur is contained in many proteins and is largely deposited in the skin. In injuries and burns sulphur metabolism is disturbed. Sulfadryl apparently stimulates the production of enzymes for the synthesis of sulphur-containing animal acids. Chas. A. Bahn.

Davids, B. **Effects of quanta-irradiation upon the eye.** Arch. f. Ophth. 148: 617-642, 1948.

In this theoretical discussion shortwave irradiation is considered as a bombardment of the eye by single corpuscles. The changes seen in the cornea and the lens occur in foci. Single cells or smaller groups of cells are affected where radiation quanta impinge on vital structures, especially of the nuclei. Four groups of quanta-effects are enumerated: effects upon the cell plasma and the cell membrane, gene-mutations, inhibition of mitotic processes, and disturbance of the structure of the chromosomes. The need to visualize the microphysical nature of these effects of radiation is emphasized.

Duke-Elder, S., Davson, H., and Maurice, D. M. **Studies on the intraocular fluids. II. The penetration of certain ions into the aqueous humour and vitreous body.** Brit. J. Ophth. 33:329-338, June, 1949.

Thiocyanate penetrates from the blood into the aqueous humor and especially the vitreous body more rapidly than either sodium, potassium or monosaccharides. Thiocyanate and the monosaccharides diffuse into the vitreous body from all the vascularized tissue surrounding it. Sodium and potassium enter predominantly from the ciliary region. In studying the factors of cell membrane permeability it was found that transference from the blood into the chambers of the eye takes place through cell bodies and not intercellular spaces. The concentration of salts in the intraocular fluids is greater than can be accounted for by a process of simple ultrafiltration; a process of secretion may be postulated.

Orwyn H. Ellis.

Fitzhugh, O. G., and Buschke, W. H. **Production of cataract in rats by beta-tetralol and other derivatives of naphthalene.** Arch. Ophth. 41:572-582, May, 1949.

Changes in the lens which were similar to those described in naphthalene poisoning in rats were produced by feeding B-tetralol. A large number of naphthalene derivatives were studied for their possible cataractogenic property. In addition to B-tetralol, 1,2,3,4-tetrahydro-2-naphthylpropionate and B-naphthylsalicylate were more potent as cataractogenic agents than was either naphthalene or B-naphthol; B-tetralol, parenterally administered, was more than twice as potent. Sulfhydryl compounds did not prevent the formation of cataract in rats fed B-tetralol.

Ralph W. Danielson.

Fontana, Giuseppe. **The action of emetine on the cornea.** Arch. di ottal. 52:113-132, May-June, 1948.

The effect of this drug on the cornea was first studied just before the first world war but the studies were rather incomplete. Corneal lesions ranging from a diffuse irregular nebular clouding to ulceration have been noted. Experiments were made with solutions varying from 1 to 5 percent. A reaction was evident in a few hours and may have been toxic, or anaphylactic. Corneal hyperesthesia, pain, and lesions of corneal nerve endings were noteworthy. The author studied the effects of 2-percent emetine injected under the conjunctiva of the bulb or the tarsus conjunctiva, and retrobulbarly. The corneal changes in most of these rabbits appeared after 48 hours and this tissue returned to normal in about 12 days. The hypothesis of anaphylaxis should receive some consideration. Francis M. Crage.

Fontana, Giuseppe. **Action of prostigmin on intraocular tension and on the diameter of the pupil.** Arch. di ottal. 52:165-181, July-Aug., 1948.

Research was carried out on three groups of rabbits and one group of patients with normal and glaucomatous eyes

among which were 22 cases of acute glaucoma, 12 of chronic glaucoma, and 2 of hydrophthalmus. There was marked reduction in tension in practically all acute and chronic glaucoma within 24 hours. In all the pupil came down to 2 mm. No effect was seen in the hydrophthalmic eyes. In the animals an iris prolapse was often partially or completely reduced within 48 hours after prostigmin especially when injected subconjunctivally. Pilocarpine and eserine were not as effective. The use of prostigmin alone, and in association with eserine, is recommended in prolapsed iris after limbal injuries.

Francis M. Crage.

Fontana, Giuseppe. **Farmocain in ophthalmology.** Arch. di ottal. 52:188-194, July-Aug., 1948.

This new anesthetic is p-butylaminobenzyl-diethylamine chloride. It is a white crystalline powder, odorless, bitter, and soluble in water and ethyl alcohol. Solutions of $\frac{1}{4}$, $\frac{1}{2}$, 1, 2, and 3-percent strength were instilled into the conjunctival sac of rabbits and patients. In the normal human eye a 1-percent solution produced a slight burning, hyperemia, and anesthesia in one minute. Anesthesia lasted for twenty minutes. When repeated twice within twenty minutes, engorgement of the conjunctival vessels took place but there was no corneal damage, change in the size of the pupil, or ocular tension. Where ulcers, keratitis, or foreign bodies were present, the burning and hyperemia were slightly increased.

Francis M. Crage.

Fralick, F. B., and Kiess, R. D. **Use of antihistaminic drugs in control of atropine dermatitis and conjunctivitis.** Arch. Ophth. 41:583-586, May, 1949.

Atropine sulfate may be continued after the development of atropine dermatitis and conjunctivitis, since the reaction is

controllable by concurrent antihistaminic therapy. Pronounced improvement with antihistaminic treatment was noted within forty-eight hours in 8 or 9 consecutive cases of atropine hypersensitivity. A combination of local and general antihistaminic therapy proved most effective. From this limited series, it would seem that the treatment of choice is a combination of oral administration of tripelennamine hydrochloride (pyribenzamine) and local use of diphenhydramine hydrochloride (benadryl). Ralph W. Danielson.

Heath, P., and Geiter, C. W. **Use of phenylephrine hydrochloride (neo-synephrine hydrochloride) in ophthalmology.** Arch. Ophth. 41:172-176, Feb., 1949.

Phenylephrine is a valuable member of the group of drugs possessing sympathomimetic activity. It may be used as a decongestive agent for the conjunctiva or globe. As a mydriatic it is used for fundus examination, in breaking adhesions of the iris to the lens, in refraction, and in some intraocular operations. Phenylephrine is of value in infiltration anesthesia as a decongestive and antispasmotic, and to prolong the action of the anesthesia. A number of less common uses are listed. The rapid absorption of substantial amounts of the drug causes marked and hazardous increase of the blood pressure. However, when applied to the anterior segment of the eye there is no significant change in either blood pressure or intraocular pressure. No harmful effects on the ocular tissues or the blood vessels have been observed nor has sensitivity or delayed healing been reported.

John C. Long.

Huggert, A. **A further support to the hypothesis that Ascher's aqueous veins contain aqueous humor.** Acta ophth. 27: 119-123, 1949.

The author dropped fluorescein into the conjunctival sac of patients with marked corneal erosions. When the aqueous was stained with the fluorescein previously localized aqueous veins were also filled with green fluid, and pressure on the eyeball was followed by an increased outflow of this fluid. The veins proximal to the point of entry of the aqueous veins remained unstained. In other eyes with a normal cornea the superficial conjunctival and episcleral vessels were stained, but pressure upon the eyeball was followed by an outflow of clear fluid.

Ray K. Daily.

Jahnke, W. **Does zinc sulfate act as an astringent?** Arch. f. Ophth. 148:775-779, 1948.

From several observations in men and rabbits the author concludes that instillation of zinc sulfate acts as an irritant or stimulant of the ocular tissues, not as an astringent. Ernst Schmerl.

Kiss, F. **The blood circulation of the eye.** Szemészet 1:1-20, 1949.

Branching and topography of the blood vessels of the eye were studied in completely injected human eyes and those of various animals. The vessel system of the ciliary body consists of two parts, the broad vessels of the ciliary processes and the narrow ones of the ciliary plexus in the region of the muscle. The first system serves the production of the aqueous humor, the latter its resorption. The ciliary plexus may be considered a second capillary region of the broad iris veins. The drainage system of the ciliary body and the canal of Schlemm have a right-angular bend with spiral course, so that drainage may be slightly retarded when the internal pressure is increased. Blood and aqueous circulation of the human eye are normally in labile balance, the latter is primarily regulated by the arterial afflux. In experiments the ciliary plexus proved

to be the most important region of re-sorption.   Gyula Lugossy.

Klang, Gunnar. **Measurements and studies of the fluorescence of the human lens in vivo.** Acta ophth. Supplement 31, 1948.

This monograph with an extensive bibliography is a report of a comprehensive investigation extending over a period of four years at the Ophthalmic Clinic in Lund, on a quantitative determination of the fluorescence of the normal human lens in vivo. This study is a preliminary to a planned investigation to determine whether changes in lens fluorescence can be established in pathological states. While fluorescence of the lens has been the subject of many investigations, the data of which are tabulated by the author, the only quantitative study of lens fluorescence preceding this report is that of Vannas and Wilska in 1935; their method of quantitative determination does not permit a study of the spectral composition of the fluorescent light, and is not applicable to cataractous lenses or work on experimental animals. In the author's investigation fluorescence was produced by ultraviolet rays of wave-length 365 μ isolated by filtration from the radiation of a mercury vapor lamp. The intensity of fluorescence was measured by comparing the light with that of a standard fluorescent screen and interposing filters until the two lights appeared of the same intensity. The instruments, experimental set-up, the technique, the sources of error, and their controls, are described in detail. The material for the investigation comprises 95 male and 163 female eyes of healthy persons, and 216 male and 102 female eyes of clinic patients treated for affections which could have no effect on the corneal or lens fluorescence. The lens fluorescence was measured in 576 eyes of 316 persons, and the corneal fluorescence on 446 eyes of 253 persons. The beam of

concentrated ultraviolet light in the lens in vivo or isolated is seen as a path of fluorescent light, which does not extend through the entire thickness of the lens but stops before it reaches the center. Since all parts of the lens fluoresce, the termination of the light path in the lens is due to the high absorption of ultraviolet by the lens; the visible path of fluorescence comes almost entirely from the anterior parts of the lens and from an anterior layer which becomes increasingly thinner with advancing age. The visible path of the fluorescent beam becomes shorter with age, because of the increased absorption of ultraviolet with age. The fluorescence of the lacrimal fluid is insignificant, and there is no fluorescence from the aqueous. Iris fluorescence was found to be greater in blue and less in brown than in green irises. The fluorescence of lens, cornea, and iris increases with age. The amount of blue in the fluorescent light from the lens increases relative to the amount of green with increasing age, and the amount of violet suffers a relative decrease. The fluorescent light contains an insignificant amount of red color. It was found that the fluorescence of lenses in the female is higher in summer and lower in winter. This seasonal variation also occurs in males but to a lower degree. There is probably a greater intensity of fluorescence of lenses in females than in males. No significant variation in fluorescence of the lens could be established relative to the refraction of the eye, refractive power of the cornea, color of the iris, or color of the hair. The author believes that the seasonal variations in fluorescence may be related to the amount of lactoflavin in the lens. While variations in fluorescence with different pathologic states of the lens will be reported in detail in a further study, it is reported here that a marked increase in fluorescence was observed in diabetic cataract at such an early stage of develop-

ment that no definite pathologic opacities could as yet be observed in the lens. However, in diabetics with incipient senile cataract no increase in fluorescence was found. (2 figures, 37 tables, 16 graphs.)

Monje, M. **The effect of helenien upon the dark adaptation.** Arch. f. Ophth. 148: 679-705, 1948.

Helenien is a lutein palmitinic acid ester obtained from Tagetes patula. After taking 375 mg. of helenien a day by mouth over a period of two weeks the sensitivity of seven subjects increased four to eight times for a period of two to three months. Ernst Schmerl.

Morone, G., and Andreani, F. **The behavior of the pupil under the action of some drugs after resection of the cervical sympathetic.** Riv. oto-neuro-oftal. 23:250-258, July-Aug., 1948.

A report is made on the pharmacodynamic behavior of the pupil in Bernard-Horner's syndrome in rabbits. The changes in the pupil were obtained by instillation of drops of atropine, cocaine and adrenalin solution. In one group of animals the pupil was dilated after a sympathectomy at the level of the second cervical neuron of Foerster and in a second group after the extirpation of the superior cervical ganglion or Foerster's third neuron. The writers are specially interested in the experiments with the adrenalin. The results in the second group agreed with Foerster's but the dilatation of the pupil in the first group did not. To explain the mydriasis the authors postulate an inhibitory system in the sympathetic pathways of which some of the fibers could originate below the superior cervical ganglion, or that some fibers independent of the main trunk bring residual mydriatic stimuli from the second neuron to the dilator of the pupil.

Melchiore Lombardo.

Pirie, A. **Ox vitreous humour. 2. Hyaluronic acid relationships.** Brit. J. Ophth. 33:271-283, May, 1949.

Studies of the physical state of hyaluronic acid in the ox vitreous and its chemical and structural relationships with the proteins of the vitreous are reported. This substance, a viscous polysaccharide, is probably concerned with the maintenance of the physical state of the vitreous body. It is found in the vitreous of all animals but perhaps in highest concentration in that of the ox. The author believes that the description of the vitreous as a tissue made up of a network of fibrils which are the prolongations of cells and permeated by a viscous fluid or jelly which easily flows out of it is justified. That there is no chemical union of the proteins with the acid is borne out by the fact that in washings with water the two are washed out at different rates and analysis of the compound which remains shows no union of the two. Hyaluronidase does not have the same destructive effect on hyaluronic in the intact vitreous as in the filtrate. It is assumed that the proteins in the vitreous help to maintain the aggregated hyaluronic acid and that the aggregated hyaluronic acid helps to maintain the vitreous structure.

Morris Kaplan.

Ross, E. J. **The formation of the intraocular fluids. Studies of the urea component of the aqueous humor.** Brit. J. Ophth. 33:310-323, May, 1949.

The concentration of urea in the aqueous and vitreous is appreciably less than in the blood plasma. This phenomenon could result from a selective secretion of urea across the barrier, utilization of urea within the eye, or the existence of a continuous outflow of aqueous from the eye, so that the rate of drainage of urea from the eye would exceed the rate of its entry. The first two of these possibilities are studied in this paper. In animals the rate

of penetration of urea into the aqueous is consistently higher than into the vitreous. That there is no deficit of urea in the aqueous and vitreous was determined by frozen section. Experiments with lenses both in vitro and in vivo and with normal and aphakic eyes showed that the utilization of urea is much too small to account for the difference. By Barany's method of ligating one carotid artery it was shown that ultrafiltration takes no part in the formation of the intraocular fluids. The difference in intraocular and in plasma urea has not been explained.

Morris Kaplan.

von Sallman, L., Evans, T. C., and Dillon, B. **Studies of the eye with radiosodium autographs.** Arch. Ophth. 41:611-626, May, 1949.

Radioautographic technics were applied to studies of the movement of Na²⁴ in the eye. A Gross method is used for frozen slices and the microscopic method of Evans for thin paraffin sections of the eye. Phases in the penetration of the tracer substance from the blood into the fluids of the eye were made visible. The regions of the ciliary body and of the optic nerve were shown as the main portals of entry. Diffusion of Na²⁴ in the vitreous and into the anterior chamber occurred at a rapid rate after intravitreal injection of the tracer. Its movement in the living eye exceeded that in the enucleated globe. The problem of absorption of electrolytes by the ciliary body was studied with Na²⁴; a conspicuous accumulation of the tracer was observed in the ciliary processes after intravitreal injection. The influence of an applied electric field on the movement of Na²⁴ in the eye was made visible by radioautography.

Ralph W. Danielson.

Sondermann, R. **The relationship between intraocular pressure, pressure in the retinal vessels and pressure of the** spinal fluid. Klin. Monatsbl. f. Augenh. 114:161-168, 1949.

The article is based on the author's theory that the intraocular pressure has its origin in increased pressure in the veins and capillaries in the uvea, which is the result of the impediment in the flow of blood through the narrow scleral channels of the vortex veins on the one hand and the small openings in the lamina cribrosa for the central retinal vein on the other hand. Progressive narrowing of these channels during the embryonic developments increases this intravenous pressure. The intraocular pressure itself compresses these channels and increases, thereby, the venous pressure. The pressure of the veins within the orbit is one of no significance for the pressure in the retinal veins. The pressure of the cerebrospinal fluid is normally negative in the skull and plays no part in originating the high venous pressure even though the vein passes through the subarachnoid spaces. The intraocular pressure prevents the signs of engorgement in the retinal veins, in spite of their high venous pressure. Intraocular and intracranial pressures are unrelated. An increase of the latter to a value greater than 4 mm., which is only possible under pathological conditions, will be a further impediment in the flow of venous blood and increase the intraocular venous pressure. One can deduce the intracranial pressure by measuring the intraocular venous pressure as well as the ocular tension under these abnormal conditions. (References.)

Sorsby, Arnold. **Concentration in the aqueous of various sulphonamides after systemic administration.** Brit. J. Ophth. 33:347-358, June, 1949.

Sulphonamide concentrations in the aqueous were determined after oral administration in rats and intravenous ad-

ministration in rabbits. In the rat, the highest concentration in the aqueous was given by sulphanilamide with successively lower readings for sulphamerazine, sulphamezathine, sulphadiazine and sulphathiazole. Seven hours after administration sulphamerazine gave the highest aqueous value with successively decreasing values for sulphamezathine, sulphanilamide, sulphadiazine and sulphathiazole. Assessment of the highest aqueous level as a percentage of the highest plasma level showed the highest value for sulphanilamide with successively lower values for sulphamerazine, sulphadiazine, sulphamezathine and sulphathiazole. In the rabbit the highest concentration in the aqueous was given by sulphadiazine with successively lower values for sulphamezathine and sulphamerazine. Sulphadiazine also proved to be the most persistent as assessed by the aqueous concentration at three hours. The highest aqueous plasma ratio was shown by sulphamezathine.

De Vincentiis, M., and Santamaria, L. **The lipidic metabolism of the retina.** Ann. di ottal. e clin. ocul. 74:523-530, Sept., 1948.

De Vincentiis and Santamaria report their study of the capacity of the rabbit's retina in vitro to oxidize butyric acid and its methylic and glyceric esters, and succinic acid and the corresponding monomethylic ester. They show that the retina has a lipidic metabolism corresponding to that of normal tissue, that is, it possesses the enzymatic systems of beta oxidation which are lacking in tumor tissue. It is suggested that the glycidic metabolism of the retina is normal in type and that the so-called neoplastic character which retinal tissue may show in vitro is due to alteration of the enzymes necessary for the aerobic desmolysis of glycides. (References.) Harry Messenger.

PHYSIOLOGIC OPTICS, REFRACTION, COLOR VISION

Balding, Grant. **Surgery for high degree of monocular astigmatism.** Eye, Ear, Nose and Throat Monthly 28:276-283, June, 1949.

A corneoscleral section was made perpendicular to the axis of the astigmatism. Although iris prolapse occurred on the third day, six months later the vision was 20/20, astigmatism was slight and the patient was able for the first time to wear glasses. He had binocular vision without discomfort. Orwyn H. Ellis.

Barnes, C. K. **Voluntary dissociation of the accommodation and the convergence faculty.** Arch. Ophth. 41:599-606, May, 1949.

Two very interesting case reports are given, and observations on the voluntary dissociation of the accommodation and convergence faculties are discussed. The first observation suggests that the psychic concept of the location of the horopter in space is primarily related to convergence, rather than to accommodation. It also suggests that the psychic magnification of near objects and minification of distant objects in excess of that based on the law of the square of the distance is predicated on convergence primarily, rather than on accommodation. The second observation involves an unusual case of fusion anomaly in which lifelong functional parallelism appeared to depend on alternation at or above the frequency of flicker. It is believed that this case may be evidence in favor of the theory of physiologic alternation as a basis of fusion. This may again revive the theory that strabismus occurs in persons who have defective synchronization of the paired oculoneural "stroboscopes." Ralph W. Danielson.

Gilbert, M., and Hopkinson, R. G. The illumination of the Snellen chart. Brit. J. Ophth., 33:305-310, May, 1949.

Studies were made on 15 adults to determine the effects of illumination on the reading of the Snellen chart. The subjects presented all types of ametropia and some emmetropia and were tested with and without their correction. The tests were conducted in illumination of 0.1, 3, and 100 foot candles. Each increase was in a ratio of 30 to 1. The results were not as startling as might be expected. An increase in illumination of the order of 10 to 1 improved the acuity by only one line on the chart, yet standard illumination for the Snellen chart seems necessary.

Morris Kaplan.

Granstrom, K. O. Transient myopia following the administration of sulfonamides. Acta ophth. 27:59-69, 1949.

A detailed description is given of seven cases of transient myopia, for a few days after the administration of sulfonamides. In one the drug was absorbed from a locally treated fistula. The changes in refraction were as high as six or seven diopters, and were identical in the two eyes. The refractive power of the cornea was unchanged. There was a decrease in the depth of the anterior chamber in two cases, and two had an aqueous flare which disappeared with the regression of the myopia. With objective stigmatoscopy it was possible to demonstrate that the refractive changes occurred axially.

Ray K. Daily.

Hartmann, E. Heterophoria and the decentering of lenses. Ann. d'ocul., 182:301-305, April, 1949.

A patient was uncomfortable with reading glasses fitted exactly to her pupillary distance, but was quite comfortable with the same lenses in a wider frame. The exophoria for near was therefore partially corrected by the prismatic action of decentered lenses. Chas. A. Bahn.

Heinsius, E. The examination of night vision with the nyctoscope. Arch. f. Ophth. 148:741-757, 1948.

In testing night vision, dark adaptation as well as visual acuity under diminished illumination should be examined. The author used phosphorescent Landolt rings or Snellen signs with definite optical qualities and measured the visual acuity in several thousand normal persons. With brightness per unit surface from about 10^{-6} to 10^{-8} stilb he finds the range of normal night vision to vary from 4 to 22 angular minutes. Ernst Schmerl.

Huggert, Arne. The form of the iso-indicial surfaces of the human crystalline lens. Acta ophth. Supplement 30, pp. 121, 1948.

This monograph, with an extensive bibliography, presents a detailed report of a four-year study carried out at the Ophthalmic Clinic in Stockholm, with the principal objectives of determining whether the surfaces of the lens or its iso-indicial surfaces have the wave-like course attributed to them theoretically by Gullstrand, and of explaining the genesis of the well-known phenomenon that a distant luminous point source of light is not perceived as a point only, but is surrounded by rays. Gullstrand, who made the most exhaustive study of this phenomenon, demonstrated that the refraction producing it is dependent upon a wave-like form of the lens surfaces or its iso-indicial surfaces. His opinion that this form could not be due to the anatomical structure, that is, the suture system of the lens, dates to a time when the complicated suture system of the adult lens nucleus was as yet unknown. Huggert, in this investigation tried 1. to ascertain radial ridges and valleys on the lens surfaces by slit-lamp examination and by examinations of the reflex images from the lens surfaces; 2. to determine the form of the iso-indicial surfaces by laboratory studies

of fixed and fresh human and cattle lenses; 3. to determine that the zones of optical discontinuity and iso-indicial surfaces in the lens are identical; and 4. to compare the shape of the star figure seen by subjective stigmatoscopy with the anatomical structure of the suture system of the anterior adult nucleus. Only the last investigation yielded definitely positive findings. Experimental errors and technical difficulties inherent in the methods employed in the first three problems tended to make their results inconclusive. No regular wave-like changes were found in the central parts of the anterior and posterior lens surfaces or their reflexes, and the findings in the peripheral portions were not certain. Direct laboratory examination of the form of the iso-indicial surfaces in fixed and fresh lenses justify the assumption that they are wave-like. A study of the correlation between the discontinuity zones of the lens and its iso-indicial surfaces indicates that within certain limits they are identical. However, slitlamp study of the surfaces and reflexes of the lens nucleus showed definitely that the adult nucleus surface has a fairly regular wavy form connected with the sutural system of the lens, and examination of fixed animal and human lenses demonstrated that the adult nucleus has 8 to 12 waves at the poles, and a larger although less distinct number near the equator. Comparative analyses of the correlation between the form of the star figures seen around small distant sources of light and the sutural figures of the lens nucleus prove the existence of such a correlation, and indicate that the form of star figures may be explained by the form of the nuclear surfaces. (27 figures, 20 tables.) Louis Daily, Jr.

Littmann, H. **The fundamentals of skiascopy.** Arch. f. Ophth. 148:658-678, 1948.

A theory of skiascopy based upon the principles of geometric optics is presented. The skiascopic shadow should

move freely over the whole pupillary area. Mirrors having a radius of from 15 to 20 mm. are preferred to the smaller ones used in electric skiascopes. The disturbances caused by the central hole can be avoided if a mirror without a hole in the glass is used. In order to determine the refraction of the foveal area, the patient should look into the direction of the examining eye. Ernst Schmerl.

Márquez, M. **The supposed torsions of the eye around the visual line in oblique directions of gaze.** An. Soc. mex. de oftal. 22:1-21 (including discussion), 1948.

This highly technical optical paper does not lend itself to abstract, but leads to the following conclusion. The fundamental error in the interpretation of consecutive images in oblique directions of gaze has been a double one. On the one hand their inclination has been attributed to turning of the eyeball upon the visual line instead of attributing it to a pseudoturning upon an oblique axis continued in Listing's plane, and on the other hand one has confused the axes of the eye, which pass through the center of rotation and which play no part in this case, with the vertical and horizontal meridians of the retina, which pass through the center of the fovea whose inclination in the same direction of gaze determines the obliquity of the consecutive image by a mechanism which is purely one of geometric optics. (10 figures, references.) W. H. Crisp.

Ribas Valero, Ramon. **The relation of the interfocal circle of the conoid of Sturm to the retinal surface.** Arch. Soc. oftal. hispano-am. 9:445-454, April, 1949.

This must be read completely.
Ray K. Daily.

Rivas Cherif, Manuel de. **High visual acuity with defective ocular refraction.** An. Soc. mex. de oftal. 22:37-54, 1948.

The author, who is a loyal admirer of Márquez's ophthalmometric method of

testing for biastigmatism, found combined astigmatism of cornea and crystalline lens in 63.3 percent of 327 cases of refraction. He urges that study of refractive errors in school children and others should not be limited to those manifesting visual defects. (9 figures, references.)

W. H. Crisp.

Sloane, A. E. **The management of early presbyopia and bilateral aphakia.** Tr. Am. Acad. Ophth. pp. 352-56, March-April, 1949.

The substitution of separate distance and near glasses for bifocals may greatly facilitate ocular comfort. In the double vision which occasionally follows bilateral cataract extraction, glasses fitting one eye for distance and the other for near may be of material service. An illustrative case of each is described. Chas. A. Bahn.

Tarle, E. **Rehabilitation of skiascopy.** Ann. d'ocul. 182:384-390, May, 1949.

The author advises the use of an electric retinoscope with flat parallel light at arm's length. A lens battery with half diopter intervals is also suggested.

Chas. A. Bahn.

5

DIAGNOSIS AND THERAPY

Ambrose, A. **A simplified perimeter of wall type.** Arch. Ophth. 41:633-636, May, 1949.

The author describes this instrument which is cheap and takes up but little room because suspended from the wall.

Ralph W. Danielson.

Arruga, H. **The utilization of binocularity for experimental investigations in therapy.** Arch. Soc. oftal. hispano-am. 9: 349-351, April, 1949.

To assess the value of new therapeutic agents Arruga uses them on one eye, while the other one serves as a control. In this manner he determined the ineffec-

tiveness of agents proposed for the arrest of cataracts, of various ointments for blepharitis, and of Filatov's tissue therapy in retinitis pigmentosa and myopic retinopathy. Ray K. Daily.

Basterra, J. **Tissue therapy in ophthalmology.** Arch. Soc. oftal. hispano-am. 9: 424-444, April, 1939.

Fifteen cases of retinal detachment, recurrent hemorrhage of the vitreous, retinitis pigmentosa, diabetic retinitis, senile macular degeneration, stubborn allergic conjunctivitis and tuberculous iridocyclitis, in which injections of cod liver oil, implantation of placenta, and injections of placental extract had no beneficial effect are briefly reported. Ray K. Daily.

Cogan, D. G., and Grant, W. M. **Treatment of pediculosis ciliaris with anticholinesterase agents.** Arch. Ophth. 41:627-628, May, 1949.

For the treatment of pediculosis ciliaris the time-honored ammoniated mercury has proved itself effective. Yet it is of considerable interest to know that the common physostigmine in the standard concentrations used for the treatment of glaucoma is just as effective. Tetraethylpyrophosphate, and presumably many other anticholinesterase compounds, are also effective. A case in which the authors had an opportunity to study the effect of physostigmine and tetraethylpyrophosphate is reported. Ralph W. Danielson.

Hallerman, W. **Operative risk and sudden increase in intraocular pressure.** Klin. Monastbl. f. Augenh. 114:144-148, 1949.

Sudden voluntary upward movements of the patient's eye lead to a considerable pull on the superior rectus muscle with subsequent rise in pressure. They should not be blindly counteracted by a superior rectus suture. A slight "give" in the pull is indicated. An injection of novocaine into the superior rectus muscle is recom-

mended for patients who are expected to be uncooperative or to press their lids together. (3 figures.)   Max Hirschfelder.

Krimsky, E. **A new hand slitlamp.** Tr. Am. Acad. Ophth. pp. 357-358, March-April, 1949.

An ordinary flashlight handle is used with two plano-convex lenses and a slit diaphragm properly adjusted. A supplementary magnifying lens is supported by a bracket.   Chas. A. Bahn.

Krimsky, E. **Concealed glare filters of supplementary lenses.** Tr. Am. Acad. Ophth. pp. 359-360, March-April, 1949.

Plastic glare filters are attached by a hinge to the temples of Zylonite frames. Each is approximately 1 cm. vertically and extends from the temple to the nose piece of each eye. Being hinged, the filters may be swung forward and nasally before the patient's vision, or backwards where they are concealed along the temples.   Chas. A. Bahn.

Krimsky, E. **Ferris-wheel attachment to Brewster type of stereoscope.** Tr. Am. Acad. Ophth. pp. 360-361, March-April, 1949.

A series of stereoscopic pictures are mounted on circular discs so that they may be rotated into the viewing position. By means of handles, these discs can be laterally regulated for ocular convergence or divergence.   Chas. A. Bahn.

Krimsky, E. **Clear-view lens frame for the Brewster stereoscope.** Tr. Am. Acad. Ophth. p. 361, March-April, 1949.

To facilitate ocular inspection especially in stereoscopic training in esotropia the author has constructed a lens frame in which the nasal sides of the frame are omitted.   Chas. A. Bahn.

Lepri, Giuseppe. **Rheumatic diseases of the eye.** Arch. di ottal. 52:133-163, May-June, 1948.

The author investigated the effect of salicylic acid injections (Mester diagnostic technique) on three groups of patients. His studies included a fourth or control group. From his studies he concluded that this diagnostic test was rather limited in its value with regard to ocular disease, but showed some cutaneous action of theoretical importance in rheumatic persons.   Francis M. Crage.

Losada Garcia, Jesus. **Details of photographic technic applied to retinography.** Arch. Soc. oftal. hispano-am. 9:459-474, April, 1949.

The author describes in detail the characteristics of the various emulsions, types of films and filters, and development techniques suitable for retinography in visible and infrared light. (5 tables, 3 formulas.)   Ray K. Daily.

Mata Lopez, Pedro. **Antibiotic therapy of ocular tuberculosis.** Arch. Soc. oftal. hispano-am. 9:415-423, April, 1949.

The literature on streptomycin is reviewed.   Ray K. Daily.

Miller, H. A. **The intraocular application of penicillin.** Ann. d'ocul. 182:378-383, May, 1949.

Recommended only in panophthalmitis, 5,000 to 10,000 units of penicillin in 0.1 to 0.2 cc. of solution is injected into the vitreous. Prolonged, severe pain follows. For infected ulcers injection into the aqueous is preferred and 0.2 to 0.3 cc. of aqueous is removed and an equal amount of penicillin solution is substituted. The injection of penicillin into Tenon's capsule with scarification of the sclera is less drastic than injection into the vitreous and apparently more effective than injections into the anterior chamber. The intraocular injection of penicillin is of uncertain value in uveitis of unknown origin and is definitely contraindicated if a tuberculin reaction is positive.
    Chas. A. Bahn.

Moore, J. I. An evaluation of the use of beta rays in ophthalmology. South. M. J. 41:1092-1094, Dec., 1948.

This paper summarizes the results of the Radium Clinic of the Wilmer Institute of the Johns Hopkins Hospital. In the past nine years beta rays have been used in the treatment of a variety of ophthalmological conditions. Almost all beta rays are absorbed by the first 3 mm. of tissue. Obviously this form of therapy is suitable only for superficial lesions of the skin of the lids, conjunctiva, cornea and sclera. The beta ray applicator used consists of a glass bulb, 5 mm. in diameter, containing radon, enclosed by brass except for the open end through which the unfiltered beta rays emerge. This active portion of the applicator is attached to a handle 35 cm. long. The side walls and end toward the operator contain sufficient brass to exclude all the beta rays, but not the gamma rays. The beta and gamma rays unfiltered pass through the open end.

Beta ray therapy is the treatment of choice in vernal conjunctivitis, vascularization of the cornea following ulcers, chemical burns, trauma or keratitis and tuberculous keratitis, and epitheliomas of the cornea and limbus. Pterygia, papillomata of the skin, warts, granulation tissue of lids and globe, keloids of lids, and heavy scarring of conjunctival flaps following glaucoma surgery are successfully treated with beta rays, but may also be treated with other types of therapy. Dense old corneal scares without vascularization, dark pigmented moles of the lids, sebaceous cysts, chalazion and xanthelasma are not helped by beta ray therapy.   Theodore M. Shapira.

Neerdam, H., and Lawoetz, B. Chemotherapy in perforating injuries of the eye. Acta ophth. 27:69-73, 1949.

On the basis of a shortened stay in the hospital and delayed and less frequent indications for enucleation in 147 perforat-

ing ocular injuries, the authors conclude that prophylactic sulfonamide therapy is effective in inhibiting intraocular infection.   Ray K. Daily.

Scholtyssek, H. Sanatorium treatment for tuberculosis of the eye in the flat country? Klin. Monatsbl. f. Augenh. 114:97-105, 1949.

The author reviews the results of sanatorium treatment in ocular tuberculosis and points out favorable results obtained in the German institution Walsrode, which is situated in a relatively low altitude. Climatic therapy of not too great an intensity is apparently desirable and the results equal those obtained in higher altitudes. (References.)
          Max Hirschfelder.

Shoemaker, R. E. Intravitreal use of streptomycin. Arch. Ophth. 41:629-632, May, 1949.

Intravitreal injection of streptomycin was used clinically in a case of bacterial endophthalmitis and appears to be a safe procedure when indicated. Unfavorable effects on the vitreous were practically nil. Retinal degeneration occurred, as in experimental animals, but one could minimize this by not exceeding the recommended dosage (800 micrograms per injection).   Ralph W. Danielson.

Stevenson, W. An applicator for beta radium D. Tr. Am. Acad. Ophth. p. 366, March-April, 1949.

The radium container is attached to two movable arms. The more distal is attached to any speculum. Thus the radium can be placed and held in any desired position without manual support.
          Chas. A. Bahn.

Stevenson, W. A new eye needle holder. Tr. Am. Acad. Ophth. p. 367, March-April, 1949.

The author uses a spring forceps simi-

lar to the Beaupre lash forceps as a needle holder. Chas. A. Bahn.

Thorpe, H. E. **Lens for deep vitreous examination.** Tr. Am. Acad. Ophth. pp. 362-363, March-April, 1949.

To facilitate more detailed examination in some types of retinal detachment and posterior vitreous abnormalities, the author modified the −55 D lens of Hruby. A hard rubber mounting which fits into an ordinary trial frame is used to prevent lashes touching the lens and also to avoid lens scratching. Reflections are minimized by lens coating. Chas. A. Bahn.

Thorpe, H. E. **Electrified suction tip.** Tr. Am. Acad. Ophth. p. 363, March-April, 1949.

To prevent annoying oozing of blood in scleral surgery the author has placed an electric screw tip connection on a suction tube. By turning on the diathermic current with the foot switch a bleeding point is at once dried and electrically coagulated. Rubber gloves are worn to insulate the operator from the diathermic current. Chas. A. Bahn.

Thorpe, H. E. **Aperture slide for binocular ophthalmoscope.** Tr. Am. Acad. Ophth. p. 363, March-April, 1949.

To avoid dazzling light reflexes with the binocular ophthalmoscope, on opaque semi-circular stop is substituted for the filters. This covers the lower half of one eye and the upper half of the other. Chas. A. Bahn.

Thorpe, H. D. **Modified Kalt electrified needle holder for inserting micropins in retinal detachment surgery.** Tr. Am. Acad. Ophth. p. 364, March-April, 1949.

The lock catch and spring were removed from the ordinary stainless steel Kalt needle holder and an electric connection was placed on the back end of the handle. Thus the needle holder may be used in retinal detachment surgery for different types of micropins. Rubber gloves are worn by the operator. Chas A. Bahn.

6
OCULAR MOTILITY

Abraham, S. V. **Etiology of nonparalytic strabismus.** Ann. West. Med. and Surg. 3:115-125, April, 1949.

The author reviews the literature on the etiology. The comparative anatomy is well presented with illustrations. The convergence mechanism is late in evolution and is still comparatively immature in the individual. The accommodation-convergence mechanism is also studied. The causal factor in nonparalytic strabismus is an interference with convergence and this functional unit determines the anatomic position of rest of the eyes. The fusion faculty is normally weak in the formative years. Orwyn H. Ellis.

Carreras Duran, B. **Internuclear paralysis.** Arch. Soc. oftal. hispano-am. 9:359-366, April, 1949.

A woman, 56 years old, is described, who had a paralysis of the right internus when looking toward the left, but not in convergence. The differential diagnosis of the various central lesions to be considered is discussed in detail. Ray K. Daily.

Drucker, A. P. **Cyclic or rhythmic oculomotor paralysis.** Eye, Ear, Nose and Throat Monthly 28:274-276, June, 1949.

A child with cyclic or rhythmic oculomotor paralysis is described and the literature reviewed. Exotropia and unilateral ptosis were also present. Orwyn H. Ellis.

Johnson, W. F. **A surgical approach to the inferior oblique muscle.** Arch. Ophth. 41:607-610, May, 1949.

After the eye is pulled far nasally, an

incision is made parallel to the external rectus muscle and extended along its lower border to the lateral fornix.

Ralph W. Danielson.

Lloyd, I. **Recession of the inferior oblique.** Brit. J. Ophth. 33:291-296, May, 1949.

In both vertical and horizontal imbalance of the eyes the action of the inferior obliques must be studied adequately. As many as 53 percent of convergent squints in children were associated with a vertical defect and 30 percent were characterized by overaction of the inferior oblique. The vertical defect must also be corrected to achieve the desired cosmetic and functional result. The indications for reducing overaction of the inferior oblique are presented. Measured recession of the muscle is always done. Partial and complete tenotomy are dismissed as unreliable. The transconjunctival route is used and the external rectus either moved aside with a hook or severed if it is to be operated upon also. The oblique is recessed 6 to 9 mm. and reattached horizontally just below the lower border of the external rectus. Twelve cases in which results were uniformly good are reported.

Morris Kaplan.

Oaks, L. W. **Divergence insufficiency as a practical problem.** Arch. Ophth. 41:562-569, May, 1949.

Divergence insufficiency is a definite clinical entity characterized by esophoria which is greater for distance than for near. It occurs, in some degree, in more than 10 percent of all patients with binocular vision who are refracted. The cause is unknown, but there seems no reason why the condition should not occur from the same causes that produce other imbalances of the horizontally acting muscles. Symptoms include headache (not relieved by correction of refractive errors), ocular fatigue and occasional diplopia,

nausea, dizziness, blurring of distant vision and panoramic headache. Diagnosis is made by use of screen-prism tests, prism duction measurements and lateral vergence tests at the near point. The relation of convergence and divergence at the near point are found not to conform to statements in some textbooks. Treatment is best accomplished by 1. proper refraction, 2. increase in the plus sphere correction, 3. use of base-out prisms, when accepted, 4. orthoptic training, and 5. surgical intervention.

Ralph W. Danielson.

Piper, H. F. **Concomitant strabismus.** Arch. f. Ophth. 148:555-616, 1948.

The author studied the phorias, fusion, depth perception and retinal correspondence in a small number of patients. Concomitant strabismus is a pathologic entity. The controlling cortical areas are weakened. Subcortical centers regulate the motor functions of the binocular unit. In horizontal strabismus the subcortical stimuli are associated with impulses for the accommodation of the single eye. In vertical strabismus the impulses are linked to stimuli for the upward and outward rotation of each eye during sleep.

Ernst Schmerl.

Remky, H. **Changes of the sensory apparatus in strabismus.** Arch. f. Ophth. 148:725-740, 1948.

The author studied a number of patients with stereoscope and perimeter. Usually a more or less pronounced central scotoma of the squinting eye could be demonstrated even in cases with bilateral amblyopia. A nervous disturbance, probably in the area of the vestibular nucleus, is suggested as the primary cause of strabismus.   Ernst Schmerl.

Urrets Zavalia, Alberto, Jr. **Disturbances of the vertical ocular muscles.** An. Soc. mex. de oftal. 22:237-262, 1948.

The author recognizes four groups of these disturbances: 1. pure concomitant vertical deviations; 2. acquired paralysis of the vertical muscles; 3. congenital unilateral or bilateral insufficiencies of the vertical muscles; and 4. dissociated vertical deviations. The first class is extremely rare or non-existent. Bielschowsky's explanation of dissociated vertical deviations is the only logically adequate one. (20 figures, chiefly clinical; references.)

W. H. Crisp.

7

CONJUNCTIVA, CORNEA, SCLERA

Arques Girones, Emilio. **Superficial punctate kerato-conjunctivitis.** Arch. Soc. oftal. hispano-am. 9:287-292, March, 1949.

The author believes that punctate keratoconjunctivitis is a neuritis of the terminal subepithelial corneal nerves, which spreads through Bowman's membrane. Since the corneal epithelium and Bowman's membrane are related embryologically to the conjunctiva they could be involved with it in a process which originates in the respiratory passages and ascends on the nasal and lacrimal mucous membrane. The characteristic piercing pain is due to the involvement of the corneal nerves and the opacities develop in Bowman's membrane at the points where it is perforated by the nerves. Occasionally the opacities extend deeper into the corneal parenchyma. Ray K. Daily.

Cameron, E. H. **The treatment of hypopyon ulcer of the cornea.** Brit. J. Ophth. 33:368-371, June, 1949.

Since the introduction of sodium sulphacetamide for the treatment of corneal abrasions in miners in Scotland the incidence of hypopyon ulcer has been greatly reduced, and the number of severe ulcerations has likewise decreased. No eye has been lost in the last seven years. In a series reviewed in 1931 there was a 10-percent loss. Improved prophylaxis and earlier treatment of minor injuries undoubtedly played a part.

Orwyn H. Ellis.

Chavarria, F. A. **Simplification of pterygium surgery.** Arch. Soc. oftal. hispano-am. 9:454-458, April, 1949.

Chavarria describes his procedure as simple and efficacious. He thoroughly dissects the head of the pterygium from the cornea, continues for four millimeters over the sclera, and then cuts the pterygium off with straight scissors, perpendicular to its fibers. The eye is bandaged, without sutures. Ray K. Daily.

Cogan, D. G. **Principles of corneal pathology: hydration properties of the cornea.** An. Soc. mex. de oftal. 22:87-98, 1948.

This is a statement, in Spanish, of material already published in English by the author. It is part of a continuing series in the Anales. W. H. Crisp.

Cogan, D. G. **Principles of corneal pathology: III. Epithelial edema and related conditions: A, epithelial edema.** An. Soc. mex. de oftal. 22:167-174, 1948.

See preceding title. W. H. Crisp.

Fierro del Rio, Leonel. **Endocrinologic studies of spring conjunctivitis.** An. Soc. mex. de oftal. 22:54-71, 1948.

Of 33 patients with vernal conjunctivitis studied, 22 showed endocrine disorders by simple physical exploration. The other patients were normal except as to the ocular disturbance. All with endocrine disturbance had gonadal insufficiency. The author believes that disturbed interaction between the sex gland and the pituitary produces a condition similar to allergy. W. H. Crisp.

Friede, R. **Megalocornea congenita, a phylogenetic anomaly.** Arch. f. Ophth. 148:761-774, 1948.

A case of congenital megalocornea and

theoretical considerations concerning its genesis are presented. The differentiation between megalocornea and hydrophthalmus is emphasized.   Ernst Schmerl.

Gasteiger, H. **Rodent ulcer of the cornea and corneal changes in scleroperikeratitis (Szilly).** Klin. Monatsbl. f. Augenh. 114:112-126, 1949.

The author observed rodent ulcer in six patients 42 to 75 years of age. Three eyes were examined histologically. Some of the patients were well-nourished and otherwise healthy; one had advanced necrosis of the sclera. Various forms of scleritis and episcleritis with involvement of the cornea are described for comparison. There is no doubt of the inflammatory character of the lesion; it is not a carcinoma-like epithelial process or trophoneurotic change. The etiology is varied; marginal ulcers, acne of the cornea, small corneal injuries, scleritis and episcleritis as well as beginning degenerative processes may be the beginning from which a rodent ulcer finally develops, if certain constitutional characteristics are favorable to its formation. (1 color plate, 8 figures, references.) Max Hirschfelder.

Harbater, M. **Scleromalacia perforans: report of a case.** Arch. Ophth. 41:183-187, Feb., 1949.

A case of scleromalacia perforans and the pathologic findings in one enucleated eye are described. The clinical appearance of the lesion and the pathologic features conformed closely to the description by Verhoeff and King. The disease accompanied chronic rheumatoid arthritis of long standing and, in the course of about twenty months, slowly progressed to involve most of the anterior portion of the sclera in a necrotizing process. The eyes have become blind as a result of an accompanying uveitis. An unusual feature of this case was an associated marginal necrosis of the cornea.   John C. Long.

Huggert, H. **Is the embryotoxon corneae posterior Axenfeld an error in development of Schlemm's canal?** Arch. f. Ophth. 148:780-786, 1948.

Two cases of embryotoxon corneae are reported. Whereas some authors ascribe the embryotoxon to the persistence of mesodermal tissue between iris and cornea, the author regards this condition as a displaced Schlemm's canal.
                    Ernst Schmerl.

Klein, M. **The lacrimal strip and the precorneal film in cases of Sjøgren's syndrome.** Brit. J. Ophth. 33:380-388, June, 1949.

The precorneal film consists of a deep mucoid layer, an intermediate lacrimal watery layer, and a thin oily layer. This is for the protection of the eye and is responsible for the brightness of the corneal surface. In kerato-conjunctivitis sicca there was a decrease in lacrimal secretion although the marginal strips of lacrimal fluid and precorneal film were present. The precorneal film seemed to be composed of the usual three elements, but the mucoid component predominated.
                    Orwyn H. Ellis.

Llorca Perez. **Two cases of bilateral crystalline dystrophy of the cornea.** Arch. Soc. oftal. hispano-am. 9:280-286, March, 1949.

Two paracentral annular opacities of the cornea, consisting almost entirely of small iridescent needle-like crystals, are reported. One patient, 12 years old, developed the opacities at the age of six. The other, a sailor, noticed them while in the service. In both the center and an area adjacent to the limbus were entirely transparent. There were no inflammatory phenomena, and no blood vessels. The arrangement of the crystals was parallel in the first case, and irregular in the other; they were in the anterior parenchymal layers. General examinations were nega-

tive, except for a slight hypercholesterolemia. The literature on fatty corneal dystrophy, and the lipoid metabolism of the cornea is reviewed. (4 figures.)

Ray K. Daily.

Meyer, F. W. **Critical report on eighteen corneal transplantations.** Klin. Monatsbl. f. Augenh. 114:131-140, 1949.

Both homoplastic and autoplastic corneal tissue may be used. The use of the latter gives no assurance of a clear transplant and is not superior to the former. Discs which were obtained as late as 42 hours post mortem from the donor eye remained clear. The status of the cornea into which the transplant material is implanted is the most important factor in the subsequent course. Clear and healthy corneal islands are a prerequisite for successful transplantation. When the first implant becomes opaque, a repetition of a transplant with a second disc is recommended. When there is a difference in the level of the endothelium between the cornea of the host and the implant, scar tissue is apt to develop. On the epithelial side the differences in level disappear.

Max Hirschfelder.

Ravn Sorensen, C. H. **A case of primary conjunctival tuberculosis.** Acta ophth. 27:113-118, 1949.

In a woman with Parinaud's conjunctivitis biopsy suggested Boeck's sarcoid and culture from the tissue revealed tubercle bacilli of the human type. Since no other tuberculous focus was revealed, the tuberculosis of the conjunctiva was assumed to be primary. The diagnostic difficulties of ocular tuberculosis are discussed. (3 figures.) Ray K. Daily.

del Rio, L. F., and Aupart, D. A. **Endocrinologic studies in spring conjunctivitis: III. Determination of urinary 17-ketosteroids.** An. Soc. mex. de oftal. 22:107-111, 1948.

Determination of the elimination in the urine of these hormonal substances was made in a group of patients with spring conjunctivitis. The figures were normal in children of less than twelve years, but below normal in patients of greater age. In this latter group the findings were regarded as significant of a gonadal lesion. In six men examination of spermatic fluid and of testicular biopsies indicated a manifest lesion of the testicle. (References.) W. H. Crisp.

Sédan-Bauby, S., Sédan, J., and Payan, H. **Corneas conserved in ice.** Ann. d'ocul. 182:364-377, May, 1949.

To determine the best method of preserving corneal transplants, the authors study four series of enucleated eyes of dogs. Those preserved in ice with humid air 24 hours after death developed massive desquamation of the epithelium with bullae on the fifth day. In those similarly preserved immediately after death the same changes took place in nine days. When the eyes were preserved in citrated autoblood, necrosis of the basal membrane was noted on the ninth day. In the fourth series paraffin oil was used as a preservative; bullae were visible on the seventh day. The anterior epithelium was least destroyed when the enucleated eyes were immediately placed in paraffin oil.

Chas. A. Bahn.

Silva, D. **Epidemic keratoconjunctivitis in Mexico.** An. Soc. mex. de oftal. 22:131-140, 1948.

Numerous outbreaks of this disorder occurred in the Mexican capital between February and April, 1947, after return of the Mexican laborers who worked in the United States during the war. The number of cases was apparently at its height in August, 1947. Sixty-eight cases are discussed from the author's experience. The article includes five excellent photomicrographs showing epithelial cell inclusions.

It is recommended that the disease be included in the list of those whose notification is required by law.   W. H. Crisp.

Sommer, G. **Total transplantation of the cornea.** Klin. Monatsbl. f. Augenh. 114:126-131, 1949.

The author reports operative procedure and course in a case of total transplantation of the cornea in a patient with an extensive total staphyloma of the cornea. A sudden opacification of the donor cornea occurred on the nineteenth day, possibly as a result of an anaphylactic tissue reaction. The eye finally had light perception and perception of handmovements.   Max Hirschfelder.

Starke, H. **Primary tuberculosis of the conjunctiva.** Klin. Monatsbl. f. Augenh. 114:107-112, 1949.

The author reviews the differential diagnosis of Parinaud's syndrome. The importance of bacteriological investigation and animal inoculation is stressed. Biopsy in a nine-year-old boy revealed tuberculous infiltration of the conjunctiva. The preauricular gland became necrotic and tubercle bacilli were found in material obtained by aspiration. Two similar cases of primary conjunctival tuberculosis are also reported. (References.)
     Max Hirschfelder.

Tavolara, L. **The gonioscopic picture of embryotoxon corneae posterius.** Boll. d'ocul. 28:91-100, Feb., 1949.

This congenital anomaly, described and named by Axenfeld in 1920, has been studied gonioscopically only by Busacca in 1948. Two of Tavolara's patients were siblings. All eyes had gonioscopically visible strands originating from different levels of the iris periphery and inserted into the opaque area of the limbus or in the brilliant streak which marked the internal border of the embryotoxon. The strands, "goniosynechiae," are ascribed

by Tavolara to a prolonged contact between the posterior corneoscleral surface and the iris which, in all cases, was hypoplastic and had but few crypts in the areas near the limbal opacities. Although embryotoxon may be a developmental anomaly the author also considers the possibility of intrauterine inflammatory disease a possible cause. (9 figures, references.)   K. W. Ascher.

8

UVEA, SYMPATHETIC DISEASE, AQUEOUS

Arjona, L. **Observations on dyschromias of the iris.** Arch. Soc. oftal. hispano-am. 9:397-404, April, 1949.

The biochemistry of the pigment elements of the eyeball, and a description of the changes which they undergo in glaucoma, diabetes, diseases of the liver, and senility are reviewed. The increase of iris pigment in association with malignant tumors of the eyeball, and melanosis of the globe in Sturge-Weber's disease are examples of hyperpigmentation. A case of choroidal sarcoma in which a pigmented focus in the iris, which had always been there, became denser and darker with the development of the intraocular tumor, is reported to demonstrate the effect of an adjacent pigmented malignant process on the metabolism of pigment cells. The increased activity of the pigment cells can be attributed either to an increase of dopa oxidase which extended beyond its source or to a cellular disturbance, which expressed itself in an increased production of dioxyphenylalanin. (2 figures.)   Ray K. Daily.

Bocci, G. **Recurrent iritis with hypopyon.** Boll. d'ocul. 28:32-40, Jan., 1949.

This disease was termed ophthalmia lenta or septic iridocyclitis by Gilbert, and recurrent uveitis due to staphylococcus allergy by Weve. The author's pa-

tient was a three-year-old boy with corneal perforation and traumatic cataract due to an explosion which also caused multiple skin lesions with secondary pyogenic infection. One week after the injury hypopyon developed and disappeared in five days with sulfonamide therapy. During the following weeks there were three recurrences. (References.)

K. W. Ascher.

Cavara, V., and Di Ferdinando, R. **Sympathetic ophthalmia and herpetic infection.** Boll. d'ocul. 28:1-16, Jan., 1949.

Two men, aged 40 years had recurrent herpetic keratouveitis of one eye only. After 16 years in one patient and five months in the other, a severe deep uveitis with keratitis developed in the previously normal fellow eye. In both cases, the first eye was enucleated and one of them was examined histologically; it showed typical sympathetic ophthalmia. Similar observations have been reported of "sympathetic" involvement after herpes zoster in the other eye. These patients, however, present the first cases of sympathetic ophthalmia after herpes febrilis of one eye. (10 photomicrographs, references).

K. W. Ascher.

Magitot, A. **Trichloracetic acid and iris prolapse.** Ann. d'ocul. 182:216-218, March, 1949.

Local application of trichloracetic acid in saturated solution is advised in old and recent iris prolapse with or without conjunctival covering and in some corneal injuries in which vitreous prolapse interferes with wound healing. It is preferred to galvanocautery which requires greater anesthesia. The cauterization may be repeated at two or three-day intervals for two or three weeks. Penicillin ointment is subsequently used. Chas. A. Bahn.

Rossi, Giuseppi. **A case of bilateral exudative choroiditis with retinal detachment and meningeal symptoms. (Harada's disease).** Arch. di ottal. 52:218-230, July-Aug., 1948.

The author reports a case of this disease, first described by Harada of Japan and so rare in Caucasians, that occurred in a young white woman in generally excellent health. The extension of the process to the anterior uveal tract was the only change which bore a relationship between this and the Vogt-Kojanagj syndrome. Another case under observation began like Coats's disease but later took on the aspects of both the Harada and Vogt-Kojanagj syndromes. The author assumes that these syndromes are different expressions of one disease which is probably infectious. Francis M. Crage.

Vergara, L., Ramírez, A., and Bolaños, F. A. **Penetrating wounds of the eyeball. Intraocular foreign bodies. Sympathetic ophthalmia.** An. Soc. mex. de oftal. 22:21-37, 1948.

Upon a review of 25 patients with penetrating wounds of the eyeball, in two of which the eyeball was enucleated after unsuccessful attempt at removal of an intraocular foreign body, and a consideration of the various theories put forward by different authors with regard to the etiology of sympathetic ophthalmia, the author speculates as to whether a nonspecific iritis prepares the field for a virosis or whether the dominant factor is sensitization to uveal pigment. (15 figures, 5 pp. references.) W. H. Crisp.

BRAZIL

SOCIEDADE DE OFTALMOLOGIA DE MINAS GERAES

The following officers were elected to serve during 1949-1950: President, Prof. Hilton Rocha; vice-president, Dr. Geraldo Queiroga; secretary, Dr. Oswaldo de Cervalho; treasurer, Dr. José Tarcísio de Castro; librarian, Dr. Ary Alvares Pires.

SOCIEDADE DE OFTALMOLOGIA DE SÃO PAULO

The following officers were chosen to serve during 1949-1950: President, Dr. Plinio Toledo Piza; vice-president, Dr. Manoel A. da Silva; general secretary, Dr. Avelino Gomes da Silva; 1st secretary, Dr. Artur Amaral Filho; treasurer, Dr. Aureliano Fonseca; files, Dr. João Carneiro.

CHILE

SOCIEDAD CHILENA DE OFTALMOLOGÍA

At its first meeting for 1949, this society reëlected the officers who had served during the past year, as follows: President, Prof. Italo Martini; vice-president, Prof. Cristobal Espildora Luque; secretary, Dr. Adrian Araya Costa; pro-secretary, Dr. Hernán Brinck; treasurer, Dr. Rene Contardo.

MEXICO

The post-graduate department of the University of Mexico announces the second series of lectures on ophthalmology. The course will last three weeks and will include lectures, demonstration of patients, and practical training in ophthalmoscopy, perimetry, campimetry, angioscotometry, tonometry, and gini-oscopy.

The course will deal especially with internal diseases of the eye, including the optic nerve and vitreous. In addition, there will be lectures and demonstrations in surgery of the eye—detachment of the retina, surgery of intraocular cysticercus, surgery of the eyeball, exenteration of the globe, Mules's operation, and so forth, as well as surgery of intraocular tumors. The course will end with practical lectures on the pathology of the eye (the technique of pathologic anatomy was studied in the first series of the course). In this second series, the student will learn by projections of microscopic sections the pathology of the internal diseases.

In addition to the General Hospital, the following institutions will coöperate: Hospital of La Luz, Hospital of the Association for the Prevention of Blindness, and the services of ophthalmology of the Juarez military and children's hospitals. The course is under the direction of Dr. M. Puig Solanes, professor of ophthalmology, University of Mexico, with the coöperation of a group of physicians of the other institutions. Enrollment price is 350 pesos.

SOCIETIES

JOINT MEETING OF PAN-AMERICAN ASSOCIATION AND N.S.P.B.

At a meeting of the executive committee of the Pan-American Association of Ophthalmology, held in New York City on May 7, 1949, it was decided to hold an interim meeting at the same time and place as the 1950 annual meeting of the National Society for the Prevention of Blindness. The dates set were March 26th to 30th and the place Miami Beach, Florida, with headquarters at the Floridian Hotel.

The following tentative program was drawn up:

Sunday, March 26th. Registration and cocktail party.

Monday, March 27th. A joint meeting of the two organizations, with the opening session at approximately 10 o'clock. The first scientific paper will be a résumé of the accomplishments of the committee on the prevention of blindness of the Pan-American Association of Ophthalmology. Dr. A. Vazquez Barriere (Montevideo, U.) is chairman. The second scientific paper, by Dr. Anderson will be on the rice diet and hypertension. This is to be discussed by Dr. Kempner. At noon there is to be an informal buffet luncheon. In the afternoon there will be a fuller discussion of the committee on the prevention of blindness, with representatives of the different countries represented on the committee speaking in the alphabetical order of those countries.

Tuesday, March 28th. Tuesday morning will be devoted to a program of the Pan-American Association of Ophthalmology: Dr. Albert D. Ruedemann (United States), "The prevention of blindness in industry from the medical standpoint"; Dr. Jorge Valdeavellano (Peru) "Observation of the effect of sunlight on the eyes"; Dr. Robison Harley and Dr. Robert Peckham (United States), "The effect of sunlight on retinal sensitivity." The fourth paper is to be a report of the committee on teaching of ophthalmology on the prevention of blindness, by Dr. Cecil O'Brien (United States) and Dr. Alberto Urrets Zavalia (Cordoba, Argentina). Tuesday afternoon will be devoted entirely to a program of the National Society for the Prevention of Blindness.

Wednesday, March 29th. In the morning the program will be arranged by the National Society for the Prevention of Blindness. In the afternoon the program, under the auspices of the Pan-American Association of Ophthalmology, will include: "Military ophthalmology in the prevention of blindness," Dr. Victor Burns, Admiral Swanson, and Colonel Stone; "Trachoma clinics," Dr. Magin A. Diez (Brazil) and Dr. Cosgrove.

Thursday, March 30th. In the morning there will be a "Glaucoma symposium" under the auspices of

the Pan-American Association of Ophthalmology. It was decided to limit this symposium to secondary glaucoma. The following division of the subject was tentatively agreed upon: Secondary to cataract; secondary to uveitis; secondary to trauma; and congenital glaucoma. The moderator is to be Dr. Conrad Berens.

Dr. Lijó Pavía of Buenos Aires has been invited to give a course this month in Mexico City on photography of the retina in black and white and color. Dr. Pavía will also speak on and demonstrate the ophthalmoscopy of the fundus with red-free light, yellow light, and other lights.

NEWS ITEMS

Edited by Donald J. Lyle, M.D.
601 Union Trust Building, Cincinnati 2

News items should reach the editor by the 12th of the month but, to receive adequate publicity, notices of postgraduate courses, meetings, and so forth should be received by the editor at least three months before the date of occurrence.

DEATHS

Dr. Eugene Orr, Nashville, Tennessee, died May 18, 1949, aged 60 years.

Dr. Homer Jonas Rhode, Reading, Pennsylvania, died June 3, 1949, aged 71 years.

Dr. William D. Rowland, Boston, Massachusetts, died July 1, 1949.

MISCELLANEOUS

CLEARING HOUSE FOR PUBLICATIONS

Later this year, the UNESCO Clearing House for Publications plans to publish a manual on the international exchange of publications and, as a supplement to this manual, a classified list of libraries, universities, scientific institutions, learned societies, and so forth throughout the world which are willing to exchange either their own publications or other publications regularly at their disposal.

All institutions which have not, as yet, sent to UNESCO details of their exchange material are urged to communicate the following information to the UNESCO Clearing House for Publications, 19 Avenue Klebrt, Paris 16°: (1) Name and full address of institution, (2) exact titles of publications offered, (3) conditions under which exchange will be made.

This information must reach UNESCO by October 1, 1949.

SOCIETIES

AOS OFFICERS

Officers of the American Ophthalmological Society elected at the recent meeting are: President, Dr. Parker Heath, Boston; vice-president Dr. John H. Dunnington, New York; secretary-treasurer, Dr. Maynard C. Wheeler, New York.

NEW YORK SOCIETY OFFICERS

The New York Society for Clinical Ophthalmology has elected the following officers for the coming year: President, Dr. Sidney A. Fox; vice-president, Dr. Samuel Gartner; recording secretary, Dr. Bernard Kronenberg; corresponding secretary, Dr. Leon H. Ehrlich; treasurer, Dr. Edward Saskin; librarian, Dr. Howard Agatston. The retiring president, Dr. Benjamin Esterman, was elected to the advisory council.

CINCINNATI OPHTHALMOLOGIC CLUB

During the school year 1948-49, the Cincinnati Ophthalmologic Club held nine meetings at which the following subjects were discussed: "Principles of extraocular muscle surgery," Dr. Hermann Burian, Boston; "Demyelinating diseases of the central nervous system with associated ophthalmic findings," Dr. McIntyre, Cincinnati.

"Industrial responsibility of the ophthalmologist," Dr. Hedwig S. Kuhn, Hammond, Indiana; "The differential diagnosis of the acute glaucomas," Dr. Peter C. Kronfeld, Chicago; "Reparative surgery," Dr. Alston Callahan, Birmingham; "Surgical anatomy of glaucoma operations," Dr. F. Bruce Fralick, Ann Arbor, Michigan; "Surgical treatment of hypermature cataract," Dr. Derrick Vail, Chicago; "Medical treatment of glaucoma and its pharmacologic basis" Dr. Harold G. Scheie, Philadelphia; "Medical treatment of ocular tuberculosis," Dr. G. B. Bietti, Pavia, Italy.

At the final meeting of the year, the following officers were elected: President, Dr. Donald J. Lyle; vice-president, Dr. K. W. Ascher; vice-president and secretary, Dr. D. J. Weintraub.

READING MEETING

On June 22nd, at the 94th meeting of the Reading Eye, Ear, Nose, and Throat Society, Dr. Frank D. Costenbader, Washington, D.C., was guest of honor. He spoke on "Pediatric ophthalmology." Other speakers were Dr. Maurice Saltzman and Dr. Matthew S. Ersner of Philadelphia, and Dr. Frederick Vastine and Dr. Harold L. Strause of Reading.

PERSONALS

TO GIVE GIFFORD LECTURE

Dr. John Dunnington, New York, will deliver the sixth annual Sanford R. Gifford Lecture on January 16, 1950, at Chicago.

TORONTO APPOINTMENTS

The University of Toronto faculty of medicine has appointed Dr. H. L. Ormsby clinical teacher in charge of eye bacteriology, and Dr. O. B. Richardson clinical teacher in charge of eye pathology.
